### Table 5 Recoveries at a concentration level of 0.05 µg L⁻¹, MDLs and repeatability precision

The examples described prove that LC/MS with IS or APCI interfaces provides instrumental detection limits, which make possible determinations of pesticides in environmental water samples at concentration levels below those of the EC Council directive 80/778/EEC (0.1 µg L⁻¹ for individual pesticide).

### 2.2 Polycyclic Aromatic Hydrocarbons

The presence of PAHs in environmental samples is a legitimate cause for concern, because some PAHs are found to be highly carcinogenic. Widespread in the environment, they originate from the incomplete combustion of organic material from both natural and anthropogenic sources; PAHs have been observed in airborne particulates, coal soot, coal tar, particulate exhaust emissions of diesel- and gasoline-powered engines, marine sediments and water samples.

Owing to the carcinogenic properties of some of these substances, selective and sensitive analytical methods are required to assess their potential health risk and their impact in the environment. PAHs are priority pollutants on both the EC (Table 1) and US EPA lists. PAH determination is mostly limited to the analysis of 16 compounds (EC, EPA) (Table 8) in drinking, surface and wastewater by HPLC and HPLC/MS. A limit of 200 ng L⁻¹ of benzo[a]pyrene (CAS 50-32-8) in drinking water is set by the Office of Water of US

* CAS registry number enclosed in parenthesis, when available. LC was performed on a 12.5 cm x 3 mm i.d. column containing 3-µm C₈-deactivated silica, using a methanol–water gradient as LC eluent. (Reproduced with permission of Elsevier Science from ref. 51 © 1996.)

EPA. The same tolerance level has been established in Directives of the Commission of the European Economic Communities (56).

A number of SRMs have been issued by the US National Institute of Standards and Technology (NIST) to assist in validating the accuracy of PAH determinations. These SRMs range from a standard solution of 16 priority pollutant PAHs in acetonitrile (SRM 1647) to a complex mixture of PAHs from coal tar (SRM 1597), from air particulate material (SRM 1649) and from diesel particulate matter (SRM 1650).

The analysis and detection of PAHs in complex environmental samples is possible by a large number of different chromatographic methods; capillary GC combined with MS has been shown to be a very selective and sensitive analytical technique, even though its applicability is limited by the low volatility of high-molecular weight PAHs. Larger derivatives are more easily analyzed by LC methods using spectrophotometric or spectrofluorimetric detectors; on the other hand, the lower efficiency of LC demands the use of more selective detection methods, such as MS. A survey of the applications of LC/MS methods in the analysis of PAHs is shown in Table 9 (56). In the past MB and PB have been the interfacing systems most frequently used for the LC/MS assay of these low-polar analytes. Generally, using the PB interface detection limits in the nanogram
range were reported for PAHs containing four or more rings;\(^\text{58,59}\) in particular, PB/MS detection affords to obtain detection limits of 0.2, 0.5, 1 and 2 ng for chrysene, benzo[\(g,h,i\)]perylene, dibenzo[\(a,h\)]anthracene and coronene (CAS 191-07-1) respectively.\(^\text{59}\) In a more recent work, the HN/APCI interface for LC/MS has been demonstrated to be the most suitable technique for trace-level determination of PAHs;\(^\text{60}\) in contrast to LC/PB/MS, the LC/HN/APCI/MS system yields a response linearity of at most three orders of magnitude and LOD in the picogram range for both low- and high-molecular-weight congeners. Positive ion APCI mass spectra of PAHs are characterized by both molecular ions and protonated molecules with no fragmentation; proton transfer from protonated water clusters leading to \(\text{MH}^+\) results to prevail over electron transfer to species such as

---

**Figure 4** LC/IS/MS ion chromatogram of the ion at \(m/z\) 244 obtained after full-scan (\(m/z\) 50–300) acquisition and injecting 25 µL of a water sample (after 4000-fold preconcentration) from the Ebro river on to a 12.5 cm × 3 mm i.d. LC column. LC eluent flow-rate, 0.3 mL min\(^{-1}\); extraction voltage, 60 V. The mass spectrum of the peak at a retention time of 20 min, shown as an inset, could be attributed to carbofuran ([M + Na]\(^+\), \(m/z\) 244). N\(_2\)\(^{2+}\) and O\(_2\)\(^{2+}\) with formation of M\(^+\) as the size of the PAHs increases. The potential of the LC/HN/APCI/MS technique was demonstrated for a NIST certified coal tar reference material (SRM 1597), which is a natural, complex mixture of PAHs isolated from coal tar and certified for concentrations of 12 PAHs ranging from naphthalene to benzo\([g,h,i]\)perylene. Internal standardization with perdeuterated PAH standards was used to perform the quantitative assay of the analytes using both the PB and APCI systems; in the first case, only seven out of 17 PAHs were detected, because of the poor transfer through the interface of the PAHs having molecular weights lower than 200 or greater than 380 Da. Conversely, using APCI interface all 17 of the target compounds were detected and accurately quantified; in general, satisfactory agreement with certified concentrations was observed when perdeuterated internal standards were used. The results of both PB and APCI measurements are summarized in Table 10.

PAHs, which are neutral low-polar compounds, cannot be detected under normal ES/MS conditions. The advantage of charge-transfer complexation to yield radical cations in solution for neutral substances for subsequent ES experiments has been demonstrated by Van Berkel et al.\(^{61,62}\) However, ES/MS techniques do
Dyes are widely used in industrial applications including textile dyes, printing inks, paint pigments, foodstuffs, plastics and cosmetics. The textile industry is the largest consumer of these chemicals and accounts for two-thirds of the dyestuff market. The manufacturing and use of dyes creates wastes, which are discharged with the effluents into the receiving waters, thus making the determination of these chemicals in water samples an important task for environmental analysis. These products represent a potential human health risk because of their toxicity or carcinogenicity; in addition, for intermediates formed during the synthesis of dyes and degradation products of dyestuffs, such as naphthylamines, substituted phenylamines or BD analogs, mutagenic and carcinogenic activity is also suspected.

Synthetic dyes are very polar or ionic and thermally labile substances, so that they are beyond the reach of capillary GC. Analytical methods for azo dyes are mostly based on HPLC with ultraviolet/visible (UV/VIS) detection; recently, the US EPA has approved several LC and LC/MS methods including Method 553 for BDs, which are carcinogenic compounds formed during synthesis of dyes.

Various types of LC/MS set-up have been proposed for the analysis of dyes, with particular attention to azo dyes (Table 11). Scarcе structural information and poor sensitivity were obtained using TS LC/MS under both PI and NI conditions; in order to better characterize the dyes, the LC/TS/MS/MS approach proved to be useful. Valuable MS data for the structural elucidation of dyes have been obtained using the LC/MS system with the PB interface; again low sensitivity with detection limits in the 0.5–5 µg range were achieved. A comparison of TS and PB mass spectra of an azo dye is shown in Figure 7. An application of capillary liquid chromatography (CLC) coupled with CFLSI/MS has been reported by Brumley et al.; seven monosulfonated dyes with azo, diazo, triarylmethane and anthraquinone groups were considered among synthetic dyes. Using CFLSI/MS as a detection system for capillary LC, mass peak-profiling at high mass resolution was demonstrated as a potentially useful tool in the structure elucidation of unknowns (Figure 8).

The feasibility of API techniques for LC/MS and LC/MS/MS ofazo dyes have been demonstrated by several authors. A pioneering study on LC/MS analysis of sulfonated azo dyes is that of Bruins et al., who used HN/APCI and IS interfacing systems in NI mode. Compounds having acidic functional groups are most suited for negative ion mode LC/MS because of their acidic properties. Disulfonated azo dyes were found to be more difficult to analyze by MS than the monosulfonated derivatives; the NI APCI spectra are given in Tables 12 and 13. By comparing the two interface systems, sensitivity for sulfonated azo dyes obtained with IS was remarkably higher than by HN/APCI. By performing liquid-phase ionization by IS, sensitivity was 10 times

2.3 Dyes

Dyes encompass structures that include (sulfonated) azo, anthraquinone, phthalocyanine, arylmethane and coumarin moieties. Azo dyes represent approximately 50% of the dyes available on the market today; they are classified in azo, diazo, triazo classes and found in various categories, e.g. acid, basic, disperse and pigments. The manufacturing and use of dyes creates wastes, which are discharged with the effluents into the receiving waters, thus making the determination of these chemicals in water samples an important task for environmental analysis. These products represent a potential human health risk because of their toxicity or carcinogenicity; in addition, for intermediates formed during the synthesis of dyes and degradation products of dyestuffs, such as naphthylamines, substituted phenylamines or BD analogs, mutagenic and carcinogenic activity is also suspected.

Synthetic dyes are very polar or ionic and thermally labile substances, so that they are beyond the reach of capillary GC. Analytical methods for azo dyes are mostly based on HPLC with ultraviolet/visible (UV/VIS) detection; recently, the US EPA has approved several LC and LC/MS methods including Method 553 for BDs, which are carcinogenic compounds formed during synthesis of dyes.

Various types of LC/MS set-up have been proposed for the analysis of dyes, with particular attention to azo dyes (Table 11). Scarcе structural information and poor sensitivity were obtained using TS LC/MS under both PI and NI conditions; in order to better characterize the dyes, the LC/TS/MS/MS approach proved to be useful. Valuable MS data for the structural elucidation of dyes have been obtained using the LC/MS system with the PB interface; again low sensitivity with detection limits in the 0.5–5 µg range were achieved. A comparison of TS and PB mass spectra of an azo dye is shown in Figure 7. An application of capillary liquid chromatography (CLC) coupled with CFLSI/MS has been reported by Brumley et al.; seven monosulfonated dyes with azo, diazo, triarylmethane and anthraquinone groups were considered among synthetic dyes. Using CFLSI/MS as a detection system for capillary LC, mass peak-profiling at high mass resolution was demonstrated as a potentially useful tool in the structure elucidation of unknowns (Figure 8).

The feasibility of API techniques for LC/MS and LC/MS/MS ofazo dyes have been demonstrated by several authors. A pioneering study on LC/MS analysis of sulfonated azo dyes is that of Bruins et al., who used HN/APCI and IS interfacing systems in NI mode. Compounds having acidic functional groups are most suited for negative ion mode LC/MS because of their acidic properties. Disulfonated azo dyes were found to be more difficult to analyze by MS than the monosulfonated derivatives; the NI APCI spectra are given in Tables 12 and 13. By comparing the two interface systems, sensitivity for sulfonated azo dyes obtained with IS was remarkably higher than by HN/APCI. By performing liquid-phase ionization by IS, sensitivity was 10 times

higher for mono- than for disulfonated derivatives and the detection of approximately 10 ng of a monosulfonated product was demonstrated in full-scan conditions. Gas-phase ionization by APCI was 20–50 times less sensitive for disulfonated azo dyes compared with monosulfonated ones. Using LC/IS/MS/MS, product-ion spectra were generated by CID from the parent ions \([M - H]^-\); the \(SO_3^−\) ion at \(m/z\) 80 was found to be a diagnostic fragment in the MS/MS analysis of this class of dyes so that SRM of the fragmentation reactions \([M - H]^- \rightarrow SO_3^−\) for each analyte could afford selective detection of the dyes, as illustrated in Figure 9.

The better suitability of IS with respect to APCI for this class of substances has been more recently confirmed by Rafols and Barceló[76] (Tables 14 and 15). On the other hand, using APCI in PI mode these authors observed a much better sensitivity towards disulfonated azo dyes than that previously found[71] likely owing to a more efficient nebulization in the APCI interface.

### 2.4 Surfactants and their Biodegradation Products in Wastewater, Surface Water and Drinking Water

Surfactants are environmentally relevant because they are extensively used and occur at high levels of concentration in water.\(^{77}\) These chemicals are used in large volumes both industrially and domestically in a broad variety of detergents and cleaning products. Surfactants have hydrophilic and hydrophobic centers both of which influence their physical and chemical properties; they may be classified as anionic surfactants, e.g. alkylbenzenesulfonates, cationic surfactants, e.g. quaternary ammonium salts, and nonionic surfactants such as those produced by reacting alkylphenols with ethylene oxide. General formulae and acronyms of the most widely used anionic and nonionic surfactants which are discussed in...

this article are reported in Table 16. Table 17 summarizes selected applications of LC/MS-based methods for the analysis of surfactants in water samples.

2.4.1 Anionic Surfactants

Anionic surfactants have been extensively studied in aquatic environments; particular attention has been paid to LAS due to their biodegradability which makes them potentially hazardous with respect to surface and groundwater, affecting also drinking water quality. LAS (Table 16) are water-soluble materials used extensively in detergent formulations as surface-active agents.

Commercial LAS materials consist of a mixture of homologs and isomers. Individual LAS homologs and isomers are identified by the length of the hydrophobic alkyl substituent and by the position of attachment of the alkyl chain to the benzene ring.

Other anionic surfactants commonly used in consumer products are AES and AS. After use, the majority of sulfonate and sulfate surfactants is disposed to sewage treatment plants (STPs); during the sewage treatment process anionic surfactants are extensively removed as the result of biodegradation processes\(^{78}\) and adsorption to solids.\(^{79}\)

Growing attention is being paid to the analysis of the degradation products of commonly used surfactants; concerning LAS, their biotransformation leads to the formation of mono- and dicarboxylic sulfophenyl acids via the \(w\)-oxidation of the alkyl chain.\(^{80}\) In support of biodegradation and ecotoxicological studies, reliable analytical methodologies are required to determine these
substances at trace levels in wastewater treatment plant influents and effluents, as well as river waters. Various analytical methods are available for the measurement of these chemicals, including simple colorimetric methods, GC and LC, as well as MS methodologies. Anionic surfactants are not sufficiently volatile to permit direct measurement by GC; as a result, they must be either derivatized to form a volatile compound or, in the case of LAS, desulfonated to form the respective linear alkylbenzenes. LC/MS has been widely applied to the measurement of these surfactants both in NP and in RP in conjunction with UV and fluorometric detection. IP RP LC, which has become the method of choice for the separation of sulfonates and their degradation products sulfophenyl carboxylates, is incompatible with MS detection (section 1.2). An elegant approach was that of coupling LC to IS/MS via a postsuppressor split with an IC system for the separation and detection of alkyl sulfates and sulfonates;136 the function of the micromembrane suppressor was that of removing over 99.9% of the IP agents required for the chromatography from the mobile phase. LC/MS has recently been applied widely to the analysis of anionic surfactants and their degradation biointermediates in water (Table 17).137–82 A comprehensive review on the use of TS interface for LC/MS and flow injection analysis/mass spectrometry (FIA/MS) analysis of these chemicals and the corresponding metabolites has been written by Schröder.83 Anionic surfactants have been detected either in PI mode as MNH4+ adduct ions in LC/TS/MS79 or as MNa+ adduct ions in LC/APCI/MS,80 or in the NI mode as deprotonated molecules using TS/MS79 or ES/MS detection systems.81 LC/MS with ES ionization has been proved ideally suited for trace-level identification and quantification of anionic surfactants:81 a quantitative LC/MS method for the determination of AES in environmental samples using IS interface has been validated for three aqueous samples, i.e. sewage influent, sewage effluent and river water. Detection of 36 components, down to ppb levels, was feasible in full-scan mode with a single injection, whereas multiple injections in SIM conditions allowed one to determine lower concentrations, limits-of-detection being about 0.01 µg L–1 for most of the analytes in river water.

2.4.2 Nonionic Surfactants

Nonionic surfactants represent the second most important class of surfactants after the anionic class. The three nonionic surfactants discussed here are those listed in Table 16. AEOs were introduced for replacing the more toxic OPEOs and NPEOs and are being used increasingly both in the household and in industry. Although APEOs and AEOs are not classified as dangerous substances, investigation on the removal efficiency of these organics by STPs and their ecotoxicological impact on aquatic life demands the development of appropriate analytical methods able to determine them in influents and effluents of STPs as well as in the natural aquatic environment. Chronic toxicity data of nonionic surfactants to aquatic life forms such as algae, fish and invertebrates range from 0.1 to 20 mg L–1, depending on substance structures and experimental conditions. In addition, more toxic degradation products of nonionic surfactants can be produced as a consequence of the metabolic activities of aquatic microbial communities. The PEG family has been indicated as primary key intermediates of the aerobic biodegradation of AEOs.78 The progressive hydrolytic shortening of the polyethoxy chain of NPEOs leading mainly to the formation of metabolites with one and two ethoxy units together with nonylphenol is the most favored pathway of AEO aerobic biodegradation.84 Nonylphenol and octylphenol have been reported to display oestrogenic activity, being suspected of altering reproduction in fish.85 NP HPLC and RP HPLC have been used to separate and determine the homologs and oligomers of nonionic surfactants by the alkyl chain and ethoxyxlate lengths. If HPLC with fluorometric detection provides the most simple and suitable technique for the analysis of these compounds in environmental samples, on the other hand LC/MS offers a unique possibility for obtaining information on the occurrence and distribution of homologs, oligomers and isomers at the ppb level. Also investigation on PEG-type compounds in the aquatic environment is made easier by the use of LC/MS methodologies; in fact, the high polarity of these metabolites combined with the lack of any chromophore group in their structures makes them not amenable to GC and LC determination. Nonionic surfactants and their biointermediates have been analyzed using TS79,86 and ES87 interfaces for LC/MS. LC/TS/MS has been proven to exhibit adequate sensitivity and selectivity for AEO determination, allowing the quantitation of total and individual alcohol ethoxylate species at the ppb level. In addition, the technique discriminates branched AEO from linear ethylene-based AEO, which may co-elute. The on-line coupling of solid phase extraction with LC/TS/MS used for the enrichment of AEOs from groundwater and wastewater allowed to quantify individual alcohol ethoxylates in the 60 ppt and 2.17 ppb range.86 In another study,79 the comparison between the results obtained by LC/TS/MS and those from flow injection analysis/thermospray/mass spectrometry (FIA/TS/MS) analyses of AEOs and their metabolites in wastewater samples showed that the chromatographic separation does not contribute significantly to the information obtainable by the direct injection of the extracts in flow injection analysis (FIA) mode.
In addition, since determination by LC/MS took 25–30 times longer than FIA/MS, this technique provided higher sample throughput.

Recently, the LC/MS technique with ES interface has been promising in terms of sensitivity and selectivity for the analysis of nonionic polyethoxylate surfactants, such as AEOs and NPEOs in various environmental aqueous samples (influent and effluent waters from STPs, river waters, drinking waters). An extraction/enrichment procedure involving the application of large water volumes (up to four liters) on a graphitized carbon black cartridge allowed for differentially elute the AEOs and NPEOs and their biointermediates according to differences in their acid strengths. The chromatographic method developed could afford the elution of all the oligomers of NPEO and of the various AEO homologs in single peaks (Figure 10), in such a way that quantitative assay was simplified and detection levels improved. The resulting detection limits for each single homolog of AEO and for NPEOs in the influent, effluent, river water and drinking water samples investigated were estimated to be 0.6, 0.02, 0.002 and 0.0002 µg L⁻¹ respectively. The selectivity and sensitivity of the method is illustrated in the chromatograms obtained by analyzing 4-liter tap water samples (Figure 11).

Efforts to characterize the degradation intermediates of nonionic surfactants in environmental matrices have increased in recent years. Concerning the metabolites of AEOs, TS/MS and thermospray tandem mass spectrometry (TS/MS/MS) techniques have been successfully used for the analysis of PEGs in various aqueous samples; mass trace analysis allowed detection of individual PEG homologs of the general empirical formula HO–(CH₂–CH₂–O)ₙH [n = 5–13] at low concentrations, whereas these compounds were not observed in the reconstructed ion chromatogram (RIC). An ES/MS-based method was shown not to be adequate for the detection of degradation products of NPEOs containing one or two ethoxy units; this result provided low accuracy in the quantitation of NPEOs in STP effluents, since the oligomer distribution of a biodegraded NPEO mixture is different from that of NPEOs in the calibrated standard solutions.

2.5 Metals, Metal Complexes and Organometallic Compounds: the Problem of Speciation

Nowadays, probably the most powerful technique for the analysis of metals and organometallic compounds at trace and sub-trace level is ICP/MS. The main features of this technique are the high element specificity, the capabilities of multielement detection, the feasibility of isotopic ratio determinations, the very low detection limits (usually in the low-ppb and ppt range) and the wide linearity range (in most cases up to 5 or 6 orders of magnitude). On the other hand, an inherent limitation of ICP/MS is that it provides only total elemental concentration information, thus denying the speciation and identification of the chemical and organometallic form of the analyte. This fact presents an important drawback in some problems of environmental concern, since the mobility of metals in the environment and their bioavailability depend on their chemical form (free metal, complexed metal, organometallic species). Consequently,
LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY IN ENVIRONMENTAL ANALYSIS

Figure 11 (a) LC/MS chromatogram obtained by injecting 3/100 of the final extract of a tap water sample (4 L). (b) Extracted chromatogram for m/z 441, 485, 529, and 573 relative to the most abundant [M + Na]\(^+\) adducts of C-16 EO oligomers. Peak numbering is the same as in Figure 10. As measured by this method, the concentrations (ng L\(^{-1}\)) were as follows: NPEOs, 61; C-12 EOs, 10; C-13 EOs, 5.6; C-14 EOs, 5.1; C-15 EOs, 1.7; C-16 EOs, 1.2; and C-18 EOs, 0.5. (c) Mass spectra of the initial part of the chromatogram showing the presence of biointermediates of polyethoxylate surfactants, i.e. PEGs, in the water sample analyzed. As an example, m/z 393 is relative to a Na\(^+\) adduct of octaethylene glycol. (Reproduced by permission of American Chemical Society from C. Crescenzi, A. Di Corcia, R. Samperi, A. Marcomini, Anal. Chem., 67, 1797–1804 © 1995.)

toxicity and environmental impact assessment cannot be adequately observed on the basis of the total concentration of an element.

On-line coupling of LC with ICP/MS permits the elemental detection capabilities of plasma MS to be added to the temporal information for the differentiation of species containing the same element, thus performing speciation analysis.\(^{(10)}\) Another advantage of LC/ICP/MS is the possibility of reducing the spectral and non-spectral interferences, which in some cases can represent a severe limitation in the ICP/MS technique. The most commonly used chromatographic mechanisms are IC and IP chromatography; in some cases, the usual RP partition mechanism has been applied and size-exclusion chromatography (SEC) has been proposed for the separation of metals bound to large molecules. The problems due to the chromatographic requirements in LC/ICP/MS have been discussed in section 1.2.

Despite the potential applications, LC/ICP/MS cannot yet be considered a routine technique, owing to the complexity and high costs of the instrumentation and to experimental difficulties, particularly for quantitative analysis; nevertheless, interesting applications to environmental analytical problems have been reported in recent literature (Table 18).\(^{(88–94)}\)

An isotope dilution mass spectrometric (IDMS) method has been proposed for the simultaneous determination of the complexes of 11 heavy metals (Ag, Cd, Cu, Mo, Ni, Pb, Ti, U, W, Zn, and Zr) with humic substances (HS).\(^{(91)}\) The application of this technique involves the addition to the sample of a known amount of a spike enriched in one of the isotopes of the element under investigation; after mixing of the sample and the spike, the resulting isotope ratio is measured with the mass spectrometer. The use of IDMS for calibration requires that two isotopes of the element to be assayed are free from interference, unless it is possible to correct them. This calibration strategy reduces the influences of short-term fluctuations, long-term drifts and matrix effects on the accuracy of the determination, since isotope ratios instead of absolute responses are used as experimental measurements. Therefore it is particularly suitable for the LC/ICP/MS technique, for which long-term drifts are not negligible owing to the long analysis times. The samples considered were brown water, i.e. natural water characterized by a high content of humic acids, groundwater, sewage and seepage water and a sample of isolated fulvic acids. The total concentrations of the heavy metals and the concentrations of the metal complexes with HS were determined, obtaining detection limits in the 5–110 ng L\(^{-1}\) range. Figure 12 shows the HPLC/ICP/IDMS chromatograms obtained using SEC and monitoring the signal of copper, zinc and molybdenum respectively, and the corresponding UV absorption profiles of a sewage water sample. The UV curve shows peaks corresponding to different fractions of HS over a broad range of molecular sizes. As it can be seen from the MS profiles, different metals are associated to single HS fractions, indicating specific
interactions between each metal and HS of a particular molecular size.

Owing to the widespread presence of chromium and arsenic compounds in the environment via industrial processes, speciation of arsenic and chromium is of particular interest, since the toxicity of these elements greatly depends upon their chemical form. The inorganic arsenic species are highly toxic, whereas the organometallic compounds are less toxic or relatively nontoxic; as for chromium, Cr(VI) is known to be very toxic and carcinogenic, whereas Cr(III) is essential to mammals. IC with ICP/MS detection has been used for the simultaneous analysis of the toxic species Cr(VI), As(III) and As(V) in presence of Cr(III) and organoarsenic compounds.\(^{92}\) Cr(III) and arsenic species did not interfere with the determination, the former being eliminated before analysis and the latter being separated from inorganic species of arsenic. The separation of Cr(VI) and the arsenic and organoarsenic species arsenobetaine (AB), monomethylarsonic acid (MMA) and dimethylarsonic acid (DMA) is shown in Figure 13. The detection limits (three times the standard deviation of the noise) were 0.5 mg L\(^{-1}\) for Cr(VI), As(III) and As(V). The method developed was applied to the analysis of wastewater and drinking water.

LC/ICP/MS has been used for the speciation of the chromium-based azo dyes Acid Blue 193 and Acid Blue 158 reported in Figure 14,\(^{93}\) with the aim to establish whether the chromium-complex dyes considered are stable in the environment as used, or if they release the metal under real chemical, physical and microbiological conditions. Cr(III) and Cr(VI) were separated on a IC column, whereas the separation of the free and complexed forms of chromium in Acid Blue 193 samples was performed in RP LC. Figure 15 shows the chromatogram of this dye with ICP/MS detection; to avoid the interference of ArC\(^+\) at \(m/z\) 52, the signal of chromium at \(m/z\) 53 was monitored. The second peak in the chromatogram has the same retention time as that of Cr(III) standard and therefore can be attributed to uncomplexed metal. The chromatogram of Acid Blue 193 obtained under the same conditions, but using UV/VIS detection shows two peaks corresponding to the first and third peaks of the ICP/MS chromatogram; these peaks can thus be assigned to species containing both the metal and the organic species. A third peak, which was not present in the ICP/MS profile, appears in the UV/VIS chromatogram; this indicates that the chromium metal was not incorporated in the dye.

ORGSn represent other analytes of interest from a toxicological point of view. As a consequence of the use of tributyltins (TBTs) and triphenyltins (TPhTs) as antifouling paints for fish nets and ship hulls, a considerable release of these compounds into the aquatic environment occurs. RP IP was the LC mechanism employed for the separation of tri-substituted tins from mono- and di-substituted forms; in particular, the method was developed for the determination of TBT and TPhT in water samples.\(^{94}\) ICP/MS detection was carried out by monitoring the tin major isotope at \(m/z\) 120. Figure 16 shows the IP chromatogram of a triethyl-, triphenyl- and TBT mixture. Since the detection limit achieved with the system used (200 ng L\(^{-1}\)) was inadequate for applicative purposes, a preconcentration procedure using C\(_{18}\) cartridges was applied on spiked water samples. In such a way, near 100% recoveries were obtained, reaching detection limits of typically 2 ng L\(^{-1}\) for both TBT and TPhT.

In addition to HPLC/ICP/MS methods, analytical methodologies based on the use of ES/IS techniques have been proposed for organometal analysis.\(^{95–97}\) The development of LC/API/MS methods originates from the lack of molecular information on the organometallic species.

which is the main drawback of ICP/MS. A pioneering study on the use of IS/MS/MS in FIA mode for the characterization of organotin species is that of Siu et al.;\(^95\) this technique proved to be extremely sensitive for TBT determination in environmental samples, the minimum detectable amount being 0.2 µg of Sn g\(^{-1}\) of sediment. On the other hand, FIA of the organometallic compounds has serious limitations when used for the assay of real sample extracts; using API techniques, the HPLC separation of the analytes is needed to achieve useful information for organometallic speciation in environmental samples. Methods based on the use of LC coupled with API/MS techniques have been applied to the organoarsenic speciation in marine certified reference materials\(^96\) and recently to the organotin speciation in sediments.\(^97\) In this work, a valuable chromatographic method using chromatographic conditions compatible with both APCI/MS and ICP/MS systems has been proposed for the determination of dibutyltin, TBT, diphenyltin and TPhT in sediment samples.\(^97\) The two LC/MS techniques were shown to be useful in providing complementary information about the organotin species present in environmental samples, combining the molecular information of the intact organometallic compounds with the high selectivity and sensitivity of ICP/MS. Using LC/ICP/MS, detectability of the organotin species was approximately 200 pg mL\(^{-1}\), whereas the LC/APCI/MS technique provided higher detection limits, being in the 50–100 ng mL\(^{-1}\) range.

3 SAMPLE TREATMENT: OFF-LINE AND ON-LINE PROCEDURES

Every instrumental method requires a chemical preconcentration if it does not fulfill the required limit

The on-line coupling of sampling treatment with LC/MS techniques represents an important advance in the development of efficient methods of extraction and analysis for organic pollutants from aqueous samples.
at trace levels. Besides sensitivity enhancement, advantages of the on-line approaches are sample throughput increase and automation capabilities, which make the overall LC/MS set-up routine for environmental analysis. Using adequate on-line trace-enrichment procedures, an improvement of analyte detectability of one or two orders of magnitude can be achieved and detection limits at nanogram per liter levels have been obtained for polar pesticides in water samples. On-line monitoring systems referred to polar pesticides have been extensively discussed in the reviews of Slobodnık et al. and of Brouwer et al.

Compared with on-line SPE, off-line SPE is more laborious and time-consuming; in addition, the problems which can be encountered in the application of this procedure are poor recoveries due to analyte losses during the solvent evaporation step. Conversely, because of the “closed” nature of an on-line set-up, contamination of the extract during treatment is reduced and losses of the target analytes do not occur. In addition, interferences present in the cartridges or the matrix have to be taken into account during the preconcentration of pollutants from water.

On-line preconcentration techniques have been also applied in LC/ICP/MS analysis of metals and organometallic compounds. Even though ICP/MS is one of the most sensitive detection system for HPLC and generally it does not require trace enrichment, in speciation analysis there is a demand for ever lower detection limits. An off-line sample preconcentration approach has been recently reported for the determination of TBT and TPhT in water, as discussed in section 2.5.

**ACKNOWLEDGMENTS**

The author gratefully thanks Professor Alessandro Mangia (University of Parma, Parma, Italy) for his valuable discussions and suggestions in the preparation of this manuscript and Dr. Lisa Elviri (University of Parma, Parma, Italy) for technical assistance.

An overview of the applications of photoluminescence techniques for the analysis of polycyclic aromatic compounds (PACs) in environmental samples is presented. The basic experimental procedures of several techniques, such as room-temperature fluorimetry, low-temperature phosphorimetry (LTP), micelle-stabilized room-temperature phosphorimetry (MSRTP), sensitized room-temperature phosphorimetry (RTP), solid-surface room-temperature phosphorimetry (SSRTP), and Shpol’skii spectrometry at 77 K are provided. Analytical figures of merit, such as linear dynamic ranges (LDRs) of calibration curves, limits of detection, and relative standard deviations (RSDs), are compared. Basic spectrofluorimeters for direct laboratory analysis of organic pollutants and instrumental systems utilized for chromatographic detection are discussed. Emphasis to portable devices using laser excitation is given to illustrate the usefulness of photoluminescence techniques for field and remote analysis of contaminated sites. Specific examples of emerging technology developed in the author’s laboratory are presented to illustrate recent advances in photoluminescence analysis of environmental samples.

1 INTRODUCTION

Environmental analysis of organic pollutants is mostly performed by chromatographic techniques. The United States Environmental Protection Agency (USEPA) 500 series for drinking water analysis is a representative example. The USEPA 500 series is summarized in Table 1. Gas chromatography (GC) and high-performance liquid chromatography (HPLC) associated with a wide variety of detection techniques are the basis of USEPA methodology. Only three methods (547, 549/549.1, and 550/550.1) use fluorescence detection. The hydrophobic nature of organic pollutants leads to concentration levels below the limit of detection (LOD) of chromatographic methods. Purge-and-trap extraction (PTE), liquid–liquid extraction (LLE) and solid–liquid extraction (SLE) techniques provide preconcentration of organic pollutants. In addition to preconcentrating the sample, extraction techniques simplify matrix composition and facilitate analytical resolution in the chromatographic column.

Although chromatography provides comprehensive methodology for a wide variety of organic pollutants, the assays are tedious, laborious, time-consuming and expensive for routine analysis of numerous samples. Elution times of 30–60 min are typical and standards must be run periodically to verify retention times. If the concentrations of target species are found to lie outside the detector’s response range, the sample must be diluted and the process repeated. On the other end of the concentration range, many samples are “zeroes”, i.e. the concentrations are below the LOD. Problems arise when laboratory procedures are scaled up to handle thousands of samples under mass screening conditions.

Therefore, there is a continuous search for simple and rapid screening techniques that can tell beforehand whether environmental samples merit the full-blown chromatographic procedure. The main trust of luminescence techniques in environmental analysis is to provide screening methodology and field analysis of organic pollutants in a direct way. Field screening techniques lead to a shorter turnaround analysis time and improve the cost effectiveness for environmental monitoring and remediation. Although a small fraction of environmental pollutants are strong luminescence emitters, which provides inherent selectivity to fluorimetry and phosphorimetry, the limited applicability often can be overcome by using derivatization or indirect methods based on effects such as quenching, complexation, enzymatic catalysis, and immunological equilibria. For instance, an excellent review on the direct and indirect analysis of pesticides in environmental samples was reported recently.

This article deals specifically with the luminescent techniques and instruments used to monitor and characterize PACs in environmental samples. PACs, which comprise...

condensed multi-ring benzenoid compounds, are important environmental pollutants originating from a wide variety of natural and anthropogenic sources. Owing to the intrinsically strong fluorescence emission from the rigid \(\pi\)-electron system of PACs, luminescent techniques have been utilized extensively for PAC identification and quantification in environmental samples. The parent homocyclic species, which contain only carbon and hydrogen, are the PAHs. Sixteen PAHs are of extreme environmental concern due to their carcinogenic effect. Their molecular structures are presented in Figure 1. In addition to PAHs, there are thousands of PACs with substituent groups such as alkyl, amino, chloro, cyano, hydroxo, oxy or thio groups. In this review, the term PAC is used to include both heterocyclic and homocyclic compounds, whereas the term PAH is used to designate only homocyclic hydrocarbons.

2 LUMINESCENCE TECHNIQUES

2.1 Fluorimetry

Room-temperature fluorimetry offers the advantages of simplicity, relatively inexpensive instrumentation, calibration curves with LDR over three to four orders of magnitude, and LOD ranging from the picograms per milliliter to the nanograms per milliliter level.\(^3\) In most cases, sample deoxygenation is not necessary and introducing the quartz sample cell into the compartment of a spectrophotofluorimeter easily performs fluorescence measurements.

A basic spectrophotofluorimeter for steady-state fluorescence measurements is equipped with a continuous wave (CW) excitation source, which is usually a xenon arc lamp operated at high pressure for continuous radiation between 200 and 800 nm. Excitation wavelengths
may be selected with bandpass filters or with an excitation monochromator. The detection system consists of: an emission monochromator, which selects the luminescence wavelength region of interest; the photodetector – usually a photomultiplier tube – which converts the luminescent radiant flux to an electrical signal; and the amplifier-readout system, which amplifies and processes the signal as required and displays it in a convenient fashion. A computer may be interfaced to the spectrofluorimeter for data acquisition and instrumental control.

A spectrofluorimeter with a dual sample–reference measurement capability may be used to compensate for instrumental distortions such as source intensity fluctuations and wavelength dependence, efficiency of the excitation wavelength selector and optical components, and wavelength dependence of detector response. Several accessories are available commercially that can be used to collect corrected excitation spectra. Improvements in signal-to-noise ratio can be obtained by using a photon-counting detection system.

Conventional fluorimetric methods – in which either the excitation or emission wavelength is set at its maximum position while the other is scanned – present limited selectivity. In the analysis of complex mixtures, the similarity and/or overlapping of broad fluorescence bands at room temperature usually interfere in the characterization process of single components. Thus, fixed-wavelength scans often do not provide either quantitative or even qualitative information for many real-world, multicomponent samples.

Several luminescence techniques have been developed to improve the selectivity of luminescence measurements. Warner et al.\(^4\)–\(^6\) have been pioneers on the use of excitation–emission matrices (EEM), lifetime and polarization measurements, and their simultaneous application to achieve a high degree of selectivity. Additionally, one can take advantage of miscellaneous methods such as quenching effects, surfactant-enhanced luminescence (micelles, etc.), chemical derivatization, and fluorescence detection in chromatographic separations such as thin-layer chromatography (TLC), paper chromatography, and HPLC.

A relatively simple approach for the simultaneous analysis of multicomponent mixtures is the synchronous excitation technique. Originally proposed by Lloyd for spectral fingerprinting of oil samples in forensic analysis, synchronous excitation was later developed by Vo-Dinh et al. for preliminary screening of PACs in environmental samples and for on-site luminescence analysis of PACs.\(^7\)–\(^9\) This approach consists of varying simultaneously both the excitation \((\lambda_{\text{exc}})\) and emission \((\lambda_{\text{em}})\) wavelengths while keeping a constant wavelength interval.

Figure 1 Chemical structures of the 16 PAHs listed on the USEPA priority pollutant list.
light interference resulting from the small $\lambda$ between them. The advantages of synchronous excitation include simplification of emission spectra, reduction of the spectral range for a given analyte, and narrowing for spectral bandwidth. Synchronous excitation can be performed with any commercial spectrophotometer in which excitation and emission monochromators can be interlocked. Spectral acquisition is performed using narrow excitation and emission slits. Although the use of narrow slits limits the sensitivity of the technique, it avoids undesired scattering and stray light interference resulting from the small $\Delta\lambda$ value.

The use of laser excitation provides several advantages to fluorimetric measurements over commercial spectrophotometers. Because the irradiance of a laser is greater than that of a conventional source with typical excitation bandpass values, laser excitation increases the intensity of fluorescence emission. Depending on the behavior of background emission upon laser excitation, an improvement in LOD can be observed. Laser-induced fluorimetry (LIF) has been employed successfully for monitoring trace organic pollutants in a wide variety of environmental samples.\(^1\)

Laser excitation is also advantageous for synchronous luminescence spectroscopy of PACs. Because the small $\Delta\lambda$ value usually employed in synchronous excitation, the use of large excitation slits with commercial spectrophotometers may create scatter and stray light interference. The fluorescence intensity of synchronous spectra, therefore, is usually limited by the use of narrow spectrometer slits. The narrow line width of the laser beam allows one to use small $\Delta\lambda$ values and still achieve high irradiance excitation. LOD at the zeptomole ($10^{-21}$ mol) level has been estimated for several PACs without previous separation from complex matrices.\(^11,\!12\)

The strong fluorescence signals exhibited by PACs contribute to the popularity of HPLC detectors. The high sensitivity of fluorescence has been augmented by the commercial availability of programmable detectors. These detectors allow the excitation and emission wavelengths to be changed throughout the chromatographic run in order to target compounds during their retention time windows. Commercial spectrophotometers can now scan at rates of many hundreds of nanometers per second, which allows on-the-fly spectra collection of chromatographic peaks if a flow cell is used. This type of spectrophotometer has been employed to collect full PAH EEM in a variety of water samples.\(^13,\!14\)

Fluorescence lifetime is another parameter that can be used to distinguish among compounds with overlapping excitation and emission spectra. Because fluorescence lifetime values range from picoseconds to microseconds, their timescale is much faster than the timescale of chromatography. Pulsed laser sources and fast detection systems allow temporal resolution of fluorescence decays during peak elution. McGown et al.\(^{15}\) have been the most active researchers in this area. On-the-fly fluorescence detection has been applied to the ultratrace-level determination of PAHs in a variety of environmentally related samples.

### 2.2 Phosphorimetry

Phosphorimetric techniques include solution LTP, MSRT, sensitized room-temperature phosphorimetry in liquid solution (SRTP), and SSRT. The interested reader is referred to comprehensive texts concerning modern phosphorimetric analysis.\(^16,\!17\)

The first generation of commercial equipment for phosphorimetric measurements consisted of a spectrophotometer equipped with a phosphoroscope for time discrimination of short-lived phenomena. Recent spectrophotometers are equipped with a pulsed lamp and a gated detection system, which allow collection of phosphorescence lifetimes in the long microsecond to millisecond time domain.

Early work in phosphorimetry was carried out at liquid nitrogen temperature (77 K). By using cryogenic equipment, the solutions were frozen to a rigid matrix to minimize the collisions competing with phosphorescence for deactivation of the triplet state. Because of the long lifetime of the triplet state, careful sample deoxygenation is recommended to avoid quenching of phosphorescence intensity. Sample deoxygenation prior to phosphorescence measurement can be accomplished by purging pure nitrogen gas through the sample solution. The main advantages of LTP are low LOD (nanomolar ranges), calibration curves with wide LDR (10\(^4\) to 10\(^6\)-fold change in analyte concentrations) and narrow phosphorescence bands that enhance selectivity.\(^18\) However, very little LTP research has been done in recent years. The lack of widespread use is mainly attributed to three reasons: the high cost of cryogenic equipment; the time-consuming sample deoxygenation; and the poor reproducibility of measurements. Although a skilled technician can obtain a RSD lower than 5%, it is not unusual to obtain RSD values as high as 20%.

Cline-Love et al.\(^{19,\!20}\) first applied MSRTP in aqueous solution as an analytical method. The method was employed to determine a wide variety of compounds, including ketones, aldehydes, alcohols, carboxylic acids, phenols, and amines. Organized media stabilization was made with the use of sodium dodecyl sulfate micelles in the presence of thallium(I) or silver(I) as a phosphorescence enhancer. Micellar solutions are colloidal aggregates or detergents that incorporate analyte molecules in their micelle cavity to protect the triplet state from collisional and vibrational deactivation. The aggregation of surfactants only occurs above a certain...
concentration, known as the critical micelle concentration (CMC). This concentration depends upon the chemical structure of the surfactant and the nature of the solvent. If no data on CMC values are available in the literature, the CMC of a particular surfactant–solvent system can be determined by fluorescence titration of a probe compound, \(^{19,20}\) capillary electrophoresis, \(^{21–23}\) or microcalorimetric titration. \(^{24}\) The use of microemulsions as organized media has also been proposed to enhance RTP emission of PAHs and pesticides in liquid solutions. \(^{25,26}\) Cline-Love et al. reported on the use of different cyclodextrin-stabilized RTP methods using \(\beta\)-cyclodextrin. \(^{27–29}\)

The main disadvantage of MSRTTP is the necessity of thorough sample deoxygenation, which results in analysis times of approximately 1 h. Shorter analysis times can be obtained by using sodium sulfide as oxygen scavenger. \(^{30}\) There are, however, considerable advantages in the use of the micelle method. In most cases, the LOD and precision of MSRTTP are similar to those obtained by LTP. The RTP analysis of PACs is facilitated by the high solubility of these species in the micellar environment. Finally, the micelle approach offers a means to conduct phosphorescence analysis in flow systems and liquid chromatography. \(^{16,17}\)

RTP detection in continuous flows and chromatographic systems can be performed also by means of SRTPL. \(^{31,32}\) In this technique, the weakly phosphorescent or nonphosphorescent analyte (donor) transfers its triplet energy to a given acceptor. A suitable acceptor should have a triplet energy lower than that of the donor, a high quantum phosphorescence yield, and a lower molar absorption in the excitation region of the donor. In addition, the energy gap between the triplet states of the donor and the acceptor should be enough to prevent significant reverse mechanisms. For instance, biacetyl has shown to be an appropriate acceptor for the analysis of polyhalogenated naphthalenes, dibenzofurans and polychlorinated biphenyls. As a detection technique in flow injection analysis and HPLC, SRTPL obtained LOD in the nanomolar range. In addition to competitive LOD, several advantages justify the use of SRTPL. Because it is an emission technique, SRTPL is inherently more sensitive than ultraviolet absorption. The background due to scattering and fluorescence impurities is negligible at the emission wavelength of biacetyl (522 nm), and it is particularly selective because most sample constituents do not promote the sensitized phosphorescence signal of the acceptor. Further research, however, is necessary to develop new acceptor–donor systems in order to expand the analytical potential of SRTPL.

In the early 1970s, Schulman and Walling \(^{33}\) reported the observation of strong RTP from a wide variety of ionic compounds adsorbed on solid substrates. Silica, alumina, paper, asbestos, and glass fiber were employed to restrict vibrational and collisional deactivation of the triplet state. Following these early reports, and certainly attracted by the simplicity of the sample procedure, a considerable number of studies on SSRTTP have been reported. \(^{16,17}\)

The classic SSRTTP procedure includes two steps: co-spotting microliters of sample and phosphorescence enhancers on the solid substrate with a microsyringe; and drying the sample in an oven (or under an infrared lamp) to minimize water quenching of phosphorescence emission. As with any other analytical method, a satisfactory LOD is obtained with low background signals. The main contribution to background emission in SSRTTP is given by the solid substrate. Many materials have been searched to find a substrate with low phosphorescence emission between 350 and 650 nm, which is the spectral region where most compounds phosphoresce. These include filter paper, silica gel, and various combinations of sodium acetate, poly(acrylic acid) and cyclodextrin with sodium halides. Among the materials investigated, filter paper has been shown to be a good, general SSRTTP substrate. Its main advantages are low cost, simplicity of handling, and availability of a wide selection of papers, which enable one to select the best substrate for specific phosphors. On the other hand, filter paper presents broad, featureless bands of excitation spectra from 200 to 400 nm, and phosphorescence spectra from 375 to 625 nm. Several attempts have been made to decrease this signal, to some extent, using solvent extraction or chromatography, chemical or heat treatment, or signal background with the help of a computer-assisted spectrophosphorimeter. \(^{16,17}\) However, the most significant reductions – which were above 90% of the original signal – were obtained with ultraviolet irradiation \(^{34}\) or a combination of water Soxhlet extraction and ultraviolet irradiation. \(^{35}\) Because the low background signal remains constant after treatment, batches of treated paper can be stored in a desiccator to be used in routine analysis.

Depending on the PAC and the phosphorescence enhancer, calibration curves with a \(10^2–10^3\)-fold change in the LDR of the analyte concentration, absolute LOD in the nanogram to subnanogram level, and RSD from 5 to 15% can be obtained with a relatively simple procedure. In certain cases, the sensitivity of SSRTTP has been improved with matrix-modifier substrates. Diethylene triaminepentaacetic acid, cyclodextrin, and sodium dodecyl sulfate are just three of the many compounds used to modify the surface of filter paper and enhance the enhancing efficiency of heavy atoms and/or PAC RTP emission. \(^{36–38}\)

If the monitoring of targeted components in complex matrices is of interest, selective external heavy-atom perturbation (SEHAP), \(^{39}\) second-derivative methods, \(^{40}\)
and synchronous excitation\(^7\) techniques can be employed to reach specific compound identification. SEHAP, which was first developed by Vo-Dinh and Hooyman,\(^{39}\) is based on the appropriate choice of a heavy atom salt, which enhances the RTP emission of the target PAC and causes phosphorescence quenching of potential phosphorescent concomitants.

Although these alternatives improve the selectivity of SSRTP, separation prior to RTP detection is convenient when dealing with complex matrices. Paper chromatography and TLC have been proposed as separation techniques for SSRTP.\(^{41,42}\) The possibility of complete analysis (separation and detection) on the same solid substrate, and the use of RTP spectral characteristics as additional parameters for compound identification, turn paper chromatography/SSRTP and thin-layer chromatography/solid-surface room-temperature phosphorimetry (TLC/SSRTP) into attractive screening tools.

SSRTP has been employed also as a detection technique for HPLC. The chromatographic fractions can be collected manually and spotted onto a RTP substrate,\(^{16,17}\) or they can be analyzed with an SSRTP automated system that completely eliminates any manual steps.\(^{43,44}\) In both cases it is possible to characterize single components in partially resolved mixtures, which simplifies the separation process in the chromatographic column. In addition to luminescent parameters such as excitation and emission wavelengths, excited-state lifetimes, synchronous excitation, and second-derivative methods, SEHAP – which is unique to SSRTP – can be used to enhance the selectivity toward a specific component. The combination of these parameters, associated with chromatographic retention times, is certainly valuable for qualitative purposes and for the simplification of chromatographic separation of complex samples.

Very few attempts have been made to improve the detection levels of PACs by laser-induced SSRTP.\(^{45,46}\) When compared with the absolute LOD obtained with commercial spectrophotometers, laser-induced SSRTP provides an improvement of approximately 1000-fold. This improvement results from the high irradiance of the laser source and the small area of solid substrate probed by the laser beam. It is possible to measure nanoliter volumes of sample with good reproducibility. Within the LDR of the studied PAC, the RSD values varied from 7% to 9.5%. The RSD obtained with a commercial spectrophotometer\(^{45}\) for the same analyte mass on the paper substrate varied from 30 to 40%. Even when small excitation slits were employed (10 nm), the irradiated area on the paper substrate excited the analyte signal and the background emission of the solid substrate. Smaller excitation slits (5 nm) resulted in unacceptable analyte-to-background signal ratios. By focusing the laser beam exclusively on the sample spot, it was possible to achieve selective excitation of the analyte, thus avoiding the excitation of background impurities. The low absolute LOD obtained by laser-induced SSRTP simplified soil sample preparation procedures. Because the evaporation of extracting solvent was not necessary to preconcentrate the sample, the direct deposition of nanoliter volumes of organic extract on the solid substrate was sufficient to determine PACs at the nanogram to picogram level.\(^{46}\)

### 2.3 Shpol’skii Spectrometry

Shpol’skii spectrometry is part of a group of high-resolution luminescence techniques that include fluorescence line narrowing,\(^{47}\) matrix isolation,\(^{48}\) and supersonic jet spectrometry.\(^{49}\) Because fluorescence line narrowing and matrix isolation can be considered complementary to Shpol’skii spectrometry, and supersonic jet spectrometry has received very little attention in current analytical literature, this review will give an overview of the application of Shpol’skii spectrometry to environmental analysis.

As mentioned previously, common room-temperature fluorescence and phosphorescence spectra of PAHs in solution show broad excitation and emission bands with typical full width at half-maximum (fwhm), values of the order of 300 cm\(^{-1}\). When PAHs are incorporated in a crystalline or polycrystalline matrix (formed at 77 K or below, using appropriate organic solvents), their excitation and luminescent spectra (fluorescence and/or phosphorescence) exhibit fine structure with sharp line (quasi-line) widths (fwhm = 1–10 cm\(^{-1}\)). Under the Shpol’skii conditions, the influence of solution inhomogeneity on the luminescence spectra of PAHs is strongly reduced by isolating the guest molecule (analyte) in a host matrix (usually \(n\)-alkanes) under low (nitrogen or helium) temperature. As a result of the highly structured orientation of solute molecules in the solid solvent, vibrationally resolved excitation and emission spectra, favorable for fingerprinting identification, can be observed. Excellent reviews have discussed the fundamental and applied aspects of Shpol’skii spectrometry.\(^{50,51}\) These include comprehensive tabulations listing the optimum solvent(s) for observing quasi-line spectra of PAHs, instrumentation, types of environmental samples, and procedures for sample cooling.

Early work in Shpol’skii spectrometry was carried out with excitation sources such as mercury-vapor discharge lamps or xenon lamps. Selection of excitation wavelength was performed with wide-band filters, interference filters, or monochromators. In recent years, the use of pump lasers and dye lasers for sample excitation has dominated the area of Shpol’skii spectrometry. Fassel et al.\(^{52–55}\) examined extensively the utilization of a tunable dye laser with the Shpol’skii technique for the analyses of PAHs
at 15–20 K in solvent-refined coal and shale oil samples. The merger of quasi-linear absorption spectra with sharp-line laser excitation sources resulted in high selectivity. This technique, which was called laser-excited Shpol’skii spectrometry (LESS), has been employed for selective identification of nitrogen-, oxygen-, and sulfur-containing PACs and isomeric PAHs.

Despite the ability of Shpol’skii spectrometry and/or LESS to provide direct identification of PAHs and PACs in crude extracts of environmental samples, their analytical potentials are still scarcely employed in chemical analysis. From the point of view of quantitative analysis, there are some critical parameters such as the freezing rate, analyte concentration, final temperature, and the necessity of working with an appropriate Shpol’skii solvent that affect the signal intensity (and bandwidth) and, consequently, the analytical results. Other problems include the limited LDR of the calibration curves and the strong scatter observed. According to Fassel and D’Silva, signal reproducibility can be solved by using a careful and reproducible freezing rate and a low analyte concentration (10⁻⁶ M or lower). The scatter is not a problem if the excitation wavelength is at least 10 nm lower than the emission wavelength, and the matrix compatibility is not an issue because n-heptane can be used with several PAHs with three- to six-ring structures. To compensate for the inner filter effect or enhancement effects, the standard addition and the internal standard method can be employed.

However, one of the main problems associated with the lack of analytical use of Shpol’skii spectrometry is the impractical sampling procedure. Two types of sampling systems are commonly used. For a temperature of 77 K, the sample is introduced into a glass or quartz tube followed by direct immersion into a Dewar flask with liquid nitrogen. The drawbacks are several, beginning with the somewhat fragile Dewar vessel. Small ice particles in the liquid nitrogen act as nucleation sites, which cause bubbling at irregular intervals and disruption of the optical path. Condensation on the outside of the Dewar flask similarly degrades the quality of the spectra. The excitation and emission light must pass through many airglass and other interfaces that scatter the exciting light, and the snowy Shpol’skii matrix is also strongly scattering. As a result of the irreproducibility from sample to sample, a RSD as high as 15–20% can be obtained. For temperatures below 15 K, cryostats or closed-cycle refrigerators are used, where the coolant can be liquid helium. However, helium closed-cycle refrigerators, Joule–Thomson miniature refrigerators, cryostats that cool the sample in cold vapor, contact cooling, etc. lack the simplicity of “dunking” the sample into liquid nitrogen.

3 FIELD MONITORING IN ENVIRONMENTAL ANALYSIS

The high coupling efficiency of lasers to fiber optics is useful in remote sensing applications. LIF with optical fibers has been used to monitor PACs in environmental samples. The specificity of LIF sensors can be improved by coating selective receptors at the distal end of the fiber optic. For instance, a highly selective detector has been reported for pyrene and other PAHs that use β-cyclodextrin as a selective receptor. Its high selectivity toward PAHs results from the hydrophobic nature of the β-cyclodextrin tip, which does not complex with other heterocyclic concomitants in contaminated water samples. Similarly to fluorescence measurements in solution, spectral overlapping of fluorescence species can be improved by temporal resolution.

A remote fiber-optic sensor has been developed to detect PAHs on a real-time basis. The device, which uses a pulsed nitrogen laser as excitation source and a gated charge-coupled device (CCD) detector at the focal plane of a spectrograph, is able to detect anthracene at nanogram per milliliter levels in 10 μs. Another instrumental system that can be used with standard cuvette sample holders or fiber-optic probes was developed recently to monitor PACs in environmental samples. It is based on laser-induced synchronous luminescence and allows several laser dyes to be used in a single scan (multidye scan), which extends the wavelength excitation range. When the laser wavelength reaches the edge of the lasing region of one dye, the computer control program pauses for a few seconds to allow manual insertion of a new dye solution. The dye exchanging process is rapid and simple because no optical realignment is necessary. The wavelength regions scanned by different laser dyes in a multidye scan need not be continuous and different Δλ values can be used. By using the fiber-optic approach, benzo[a]pyrene and perylene were detected at the parts-per-billion (ng mL⁻¹) level in a water sample.

A SSRTP fiber-optic probe has been developed recently for the analysis of PACs in contaminated waters. A pulsed nitrogen laser and a dye laser were used as excitation sources. At the tip of a bifurcated fiber-optic bundle, the RTP probe, which consisted of a cavity between two cylindrical parts attached by concentric incised threads, provides the paper substrate compartment. A hole at the distal end of the probe allows the entry of water into the substrate cavity. By dipping the probe into the water sample, the paper substrate is imbibed with water, which is retained on the solid substrate. RTP measurement is performed after removing the probe from the water sample and drying the substrate under an infrared lamp. Several PAHs and nitrogen...
heterocyclic compounds of environmental importance were determined at the parts-per-billion level.\(^{64,65}\)

Although the SSRTP probe does not allow in situ analysis of water samples, fiber-optic sensing based on phosphorescence emission offers higher selectivity over fluorescence optosensing. The higher selectivity is based on the fact that phosphorescence is less common than fluorescence at room temperature. The interference from short-lived scattering and possible fluorescence signals can be avoided by using appropriate delay times after the excitation pulse. This is particularly useful in reducing or even eliminating the spectral interference of humic and fulvic acids, a problem usually encountered with fluorescence optosensing of PACs.\(^{58–62}\) SEHAP can provide enhanced selectivity for the direct determination of a target compound in complex mixtures with several luminescent (fluorescent and/or phosphorescent) compounds. Other advantages include the use of low-cost optical fibers (phosphorescence occurs at emission wavelengths longer than 450 nm) and relatively-low-cost instrumentation for time-resolved measurements, because triplet-excited lifetimes are in the millisecond (or higher) time domain and, therefore, they are easier to resolve instrumentally than fluorescence lifetimes.

The RTP probe presents unique features for field analysis. Its design minimizes contact between the sample and quenching species such as oxygen and atmospheric humidity. By using appropriate heavy-atom salts, the excitation wavelengths of the compounds of interest can be shifted to overlap the excitation line of the laser source and avoid the change in excitation source. By spotting standard solutions on the paper substrate imbibed with the sample, on-site identification and determination of compounds can be performed. By changing the paper substrate in the sample compartment, the RTP probe can be used for an infinite number of measurements, which reduces analysis time and cost when compared to coated fiber-optic sensors.

4 NEW TRENDS IN LUMINESCENCE ANALYSIS OF ENVIRONMENTAL SAMPLES

SLE is nowadays the recommended method for the sample pretreatment of complex matrices, and the use of LLE has dropped dramatically following obligatory reduction of chlorinated solvent usage in analytical laboratories. In water analysis, SLE concentrates the organic pollutants by sorption onto an octadecyl (C\(_{18}\)) organic phase chemically bonded to silica particles. When compared to LLE, SLE reduces solvent consumption, has fewer steps, saves labor, provides better extracting efficiency, prevents emulsions, enables easy sample collection, and is more amenable to automation.\(^{66}\) SLE, however, presents certain disadvantages for chromatographic analysis. The mechanism of isolation on C\(_{18}\) membranes is van der Waals’ forces (also called nonpolar, hydrophobic or reversed-phase interactions) and occasionally secondary interactions such as hydrogen bonding and dipole–dipole interactions. Nonreversed-phase interactions (hydrogen bonding and dipole–dipole interactions) result from unreacted (residual) silanol and siloxane groups on the surface of octadecyl silica phases. These interactions are stronger than van der Waals’ forces and can cause poor analyte recovery. An additional consideration for efficient analyte elution is the removal of water from the C\(_{18}\) sorbent. In order for the elution solvent to wet effectively the bed of the sorbent, it is necessary to remove the water in the void volume, trapped water, and water sorbed to the silica. Air or a vacuum may be used to remove the majority of the water in the void volume. The water in the smallest pores and water that is sorbed to the silica surface will be tightly trapped or bound to the silica surface. The bound water may be removed by drying the sorbent under a vacuum (25 mmHg) for at least 15 min. Another approach is to use an eluting solvent that is miscible with water. For instance, a mixture of methylene chloride–ethyl acetate (1 : 1) gives recoveries of 85–95% for the 46 pollutants listed in the USEPA method 525.1.\(^{1}\) Methylene chloride, on the other hand, gives low analyte recoveries (40–70%). These low recoveries most likely arise from the inability of methylene chloride to displace and penetrate the water saturating the internal pores of the silica phase. Finally, a source of potential contamination in SLE is the presence of impurities in the cartridge or disk (such as phthalate esters) that leach from the adsorbing material into ethyl acetate and methylene chloride and produce a variable background in the water sample.

A new approach for screening PACs in water samples is being developed in our laboratory.\(^{67–69}\) The new analytical tool combines SLE with SSRTP. Because the analysis of PACs is performed on the adsorbing material, the drawbacks associated with SLE procedures are eliminated. The ability of SSRTP to measure nanogram to subnanogram levels of PACs on the extraction membrane allows one to use relatively small water sample volumes. This is advantageous because it simplifies the extraction procedure and reduces analysis time. Figure 2 shows the apparatus employed for 10-mL SLE of water samples. Conventional water SLE procedures, which rely on processing 1 L of water through the extraction membrane, require bulky glassware, a vacuum pump, an oven to dry the sample following water extraction, and relatively long analysis times (~1 h per sample).
By using syringes and stainless-steel filter holders, the bulky glassware and vacuum pump are removed from the extraction procedure. The oven-drying step is substituted by air sample drying, which employs positive pressure to remove water excess from the extraction syringe. As a result, analysis times of 3–5 min per sample are obtained, which are extremely attractive for screening large number of samples. The LOD values for the 16 PAHs of the USEPA priority list (see Figure 1) were estimated with a commercial spectrofluorimeter at the picogram per milliliter level. LOD values at the parts-per-trillion level were also estimated for polychlorinated biphenyls and dibenzofurans. Selective identification of total PAHs, polychlorinated biphenyls and dibenzofurans was obtained by appropriate selection of heavy-atom salt and delay and gate times. Although further studies are necessary to prove solid–liquid extraction/room-temperature phosphorimetry (SLE/RTP) as a reliable analytical tool, the simplicity of the new experimental procedure, the analytical figures of merit and the selectivity of SLE/RTP show its analytical potential for initial screening of numerous water samples.

A similar approach is being developed by Hurtubise et al. at the University of Wyoming (WI, USA). Whatman 1PS filter paper is used as the solid-phase microextraction medium for PAHs in water. This filter paper is based on the same cellulose substrate as Whatman no. 1, but it is impregnated with silicone oil in the presence of an organotin catalyst. It is believed that the tin remaining in the coating may act as a heavy atom, facilitating the acquisition of RTP spectra. The silicone provides a hydrophobic surface onto which PAHs can be extracted from water. The PAHs on the surface of the Whatman 1PS paper are detected at the nanogram per milliliter level by using fluorescence and/or phosphorescence measurements.

A fiber-optic probe was employed recently in our laboratory to test a new sampling procedure for photoluminescence measurements at 77 K. The probe consisted of one excitation fiber surrounded by six emission fibers. The launch and collection fibers were bundled with vacuum epoxy. Figure 3 shows a schematic diagram of the fiber-optic probe and measuring procedure. A 1-mL aliquot of sample solution was introduced into a 5-mL Pyrex test tube, and the test tube was then introduced into a container with liquid nitrogen. Figure 4 shows the instrumental system used with the fiber-optic probe. The intensified in front of the CCD chip acts as a super-fast shutter, capable of operating on a nanosecond timescale. The parameters for data acquisition (gate delay, gate width, and the gate step) are entered in a computer, using

appropriate software. The software sends these intensifier set-up details via a general purpose interface bus (GPIB) interface to the pulse generator. Once triggered by the laser, the pulse generator uses this information to determine when the image intensifier in the detector head is gated on (gate delay), for how long it is gated on (gate width), and the duration of the steps by which the gate delay is progressively increased in the course of the sequence of acquisitions (gate step). The intensifier is gated on for the duration of the pulse, allowing the CCD to acquire data. When the intensifier is gated off, the acquired data are transferred from the detector head to the controller card (32-bit Intelligent Bus-Mastering PCI card) in the computer. With this instrument, it is possible to collect wavelength–time matrices in a few nanoseconds. The entire sample procedure – which includes sample freezing, spectra collection, and probe rinsing for the following measurement – takes less than 5 min, which is extremely attractive for routine screening. Because the fiber-optic probe eliminates scattering surfaces between sample excitation and fluorescence collection, the RSD for several PAHs was excellent, varying from 2% (pyrene) to 7% (phenanthrene). Table 2 shows the LDR and LOD obtained with the new system using optimum delay and gate times. The appropriate choice of delay and gate times for each PAH was based on the analyte and background fluorescence lifetimes. Compounds with long lifetimes, such as pyrene, allow the collection of strong PAH fluorescence emission at delay times where background contribution is negligible (approximately equal to instrumental noise). On the other hand, for a PAH such as chrysene, the complete time resolution of background emission is limited by the short fluorescence decay of the PAH. Therefore, the choice of a delay time for the best analyte-to-background signal ratio involves a compromise between the relative intensities of analyte and background signals.

In addition to the improvement in analyte-to-background signal ratios, time resolution enhances the selectivity of LESS toward the target PAH. Figure 5 shows the fluorescence spectrum of benzo[a]pyrene recorded from a standard solution in n-heptane. Figure 6 shows the low-temperature fluorescence spectrum of a small volume of oil sample spiked into n-heptane. By selecting the delay (10 ns) and gate (50 ns) times based on the fluorescence lifetime of benzo[a]pyrene (39.9 ns), it was possible to identify the target PAH in a direct way.

Several separation techniques have been coupled to Shpol'skii spectrometry for the analysis of PAHs in “real world” samples. In the specific case of water

Sample preparation, LLE has been the approach used the most.\(^{50}\) In addition to the previously discussed advantages of SLE over LLE, the combination of SLE with LESS presents a unique feature, which is obtained if the eluting and the Shpol'skii solvent are the same. A three-step sample procedure (extraction, elution, and fluorescence measurement) is then obtained, which provides a quick and simple method of analysis. Table 3 shows the LOD for several compounds obtained by SLE coupled with LESS. The preconcentration factors achieved by SLE, associated with the small volume of organic solvent used for PAH elution and fluorescence measurement, result in LOD at the femtogram per milliliter level. These values compare favorably with those obtained by room-temperature fluorimetry, where several factors such as lack of scatter, large excited sample volume, spectral bandwidth, and depth of excitation contribute to very low detection levels.\(^{3}\)

5 FINAL REMARKS

The monitoring and characterization of PACs in complex environmental samples require a battery of analytical methods and instrumentation. Laboratory analysis of PACs is mostly performed by GC and HPLC, which can provide complete characterization of complex matrices after sample clean-up and preconcentration. Because chemical analysis is increasingly moving from the traditional laboratory setting toward in situ applications, analytical chemistry faces the challenge of developing the tools for on-line and field monitoring in real-time bases.

Photoluminescence is inherently a multiparameter phenomenon. The examples presented in this review demonstrate the main thrust of photoluminescence in environmental analysis, which is obviously related to the uniqueness of its multidimensional nature. The measurement of fluorescence and/or phosphorescence from a sample involves the simultaneous use of excitation and emission wavelengths and luminescence lifetimes. The appropriate combination of these parameters, sometimes associated with polarization measurements, chemical derivatization, and/or measurement of effects such as quenching, enzymatic catalysis, and immunochemical equilibrium, provides highly selective and sensitive techniques. To measure the various luminescent parameters and explore the full potential of photoluminescence techniques, the analyst should use a combination of commercial spectrofluorimeters and instrumental set-ups with laser excitation sources, fiber optics, monochromators and spectrographs, photodetectors, and imaging systems. The continuous development of luminescent techniques and instrumentation, associated with the parallel development of novel computer algorithms for reduction and interpretation of large data sets, provides a valuable number of spectrochemical tools for direct laboratory determination of PACs and remote sensing under field conditions.

Mercury Analysis in Environmental Samples by Cold Vapor Techniques

Kim A. Anderson
Oregon State University, Corvallis, USA

1 INTRODUCTION

A naturally occurring element, mercury’s unique properties have been valued for several centuries. The metal cycles in the environment as a result of natural and anthropogenic activities. Mercury in most environmental matrices occurs at low concentrations; therefore, sensitive analytical methods are necessary for its detection. Mercury is a known toxicant, and is known to bioaccumulate especially in the aquatic food web. In the 1950s and 1960s two major epidemics of methylmercury poisoning through fish consumption occurred in Minamata Bay and Niigata (both in Japan), where thousands of people were affected. Environmental monitoring of mercury is meaningful. Due to the complexity of mercury biogeochemical cycling, monitoring of mercury requires the analysis of many different matrix types, such as air, waters, soils, sediments, sludges, as well as range of biological matrices. Mercury determination is complicated by the multiple oxidation states of naturally occurring mercury but also because of biotic and abiotic methylation and the volatility of several forms of mercury(I and II). Mercury is unique among the metals because of its large vapor pressure at ambient conditions. Mercuric ions in solution can be reduced by tin(II), or sodium borohydride to produce volatile elemental mercury, referred to as the cold vapor process. The mercury is swept out of solution with a carrier gas (in the gas of sodium borohydride, the byproduct is hydrogen) into the cell (or torch) where the atomic absorption (or fluorescence, or emission) is measured. The cold vapor technique removes the mercury from the sample matrix, concentrates the mercury in the analytical sample into a small plug of carrier gas, and provides for a relatively long residence time. Detection limits vary depending on the instrument but are in the submicrogram to nanogram per liter range for atomic absorption spectrometry (AAS), atomic fluorescence spectrometry (AFS), and inductively coupled plasma atomic emission spectrometry (ICP AES).

The accurate, precise, and automated determination of mercury in biological and environmental samples is complex, not only because of the various oxidation states of mercury (i.e. 0, I and II), but also because of biotic and abiotic methylation and the volatility of several forms of mercury(I and II).
In addition, the technique concentrates all the mercury from the entire sample into a small plug within the carrier gas. Sample sizes as large as 50 mL are routinely used; mercury from the entire 50 mL is purged out as volatile mercury, and aspirated into an AAS, AFS, or ICPAES instrument. This represents a huge increase in sample size as compared to typical aspiration sample delivery. This process is referred to as the cold vapor mercury analysis technique. The sensitivity is several orders of magnitude better than for conventional AAS, AFS, or ICPAES analysis.

2 CHEMISTRY

2.1 Properties of Mercury

The heavy metal mercury (Hg), atomic number 80 and atomic weight 200.59, is a silver-white heavy liquid at typical ambient temperatures and pressures (specific gravity 13.5 kg L\(^{-1}\) CAS 7439-97-6). Mercury’s melting point is \(-38.89^\circ\)C and boiling point (bp) is 357.25°C under atmospheric pressure. Mercury is the only metal which is a liquid at room temperature. The reason for this is that mercury has a very high ionization energy (first ionization potential = 1007 kJ mol\(^{-1}\))(1) which makes it difficult for electrons to participate in metallic bonding. Mercury metal has a high vapor pressure (0.16 Pa at 20°C), and vaporizes readily under ambient conditions; a saturated atmosphere would contain approximately 15 mg Hg m\(^{-3}\) at 20°C.(2)

Elemental mercury dissolves numerous other metals (gold, silver, platinum, uranium, copper, lead, sodium, and potassium) to alloys, called amalgams. Mercury is unusual among metals because it tends to form covalent bonds rather than ionic bonds.

2.2 Properties of Mercury Compounds

Mercury can exist in three oxidation states: Hg\(^0\) (metallic), Hg\(^{2+}\) (mercurous), and Hg\(^{2+}\) (mercuric), equivalently designated as Hg\(^0\), Hg\(^{2+}\) and Hg\(^{2+}\). The properties and chemical reactivity of mercury strongly depend on the oxidation state. Mercurous and mercuric mercury form numerous inorganic and organic chemical compounds; however, mercurous mercury is rarely stable under typical environmental conditions. Only a few mercurous compounds are known; mercury(I) is unique in that these compounds contain the mercurous ion (Hg–Hg)\(^{2+}\), not Hg\(^{+}\). However, halides of mercurous mercury form readily, and Hg\(_2\)Cl\(_2\) is used extensively in chemical applications (often referred to by its trivial name, calomel).

Most mercury in the environment, including waters, soils, sediments and biota, occurs in the forms of inorganic mercuric salts and organomercurics. Organomercurics are defined by the presence of a covalent Hg–C bond. The mercury compounds most likely to be found in the environment (atmospheric mercury being the exception) include the following: mercuric salts, for example HgCl\(_2\), Hg(OH)\(_2\), and HgS, methymercury compounds, for example methylmercuric chloride (CH\(_3\)HgCl) and methylmercuric hydroxide (CH\(_3\)HgOH); and, to a lesser extent, dimethylmercury and phenylmercury.(3) Most organomercurics are not readily soluble and do not react with weak acids or bases due to the low affinity of mercury for oxygen bonded to carbon. However, methylmercuric hydroxide (CH\(_3\)HgOH) is highly soluble due to the strong hydrogen bonding capability of the hydroxide group. The mercuric salts vary widely in solubility. HgCl\(_2\), Hg(NO\(_3\))\(_2\), and Hg(ClO\(_4\))\(_2\) are very soluble in water, whereas HgS is insoluble (\(K_{sp} \approx 10^{-54}\)). Further information on the chemistry of mercury can be found in the excellent discussions by Mason et al.(4) and by Nriagu.(5)

3 DISTRIBUTION AND USES OF MERCURY

3.1 Sources of Mercury in the Environment

As a naturally occurring element, mercury cannot be created or destroyed; mercury is present throughout the environment in both environmental media and biota. Mercury is found at trace levels in many minerals, with continental rocks containing an average of 80 mg Hg per kilogram (i.e. ppb).(6) Soil mercury concentrations may vary dramatically depending on the local geology and industry; typical soils are reported to contain 0.01–0.5 ppm.(7) Mercury is mined as the bright red ore cinnabar (HgS) predominantly in Russia, Spain, Mexico, and Algeria. Mercury is normally present in plant tissues in the range 30–700 ppb.(8) Mercury concentrations in waters vary, typical levels are reported as ranging from 0.0001 to 2.8 \(\mu\)g Hg L\(^{-1}\) in fresh water, and from 0.01 to 0.22 \(\mu\)g Hg L\(^{-1}\) in seawater.(7) The mercury content in air varies dramatically depending on the source, and is influenced heavily by volcanic and anthropogenic activities. Mercury in clean air is reported at <0.01 ng m\(^{-3}\), whereas contaminated air values for mercury range from 0.009–2.8 ng m\(^{-3}\) in Europe, 0.07–38 ng m\(^{-3}\) in North America, 1.6 ng m\(^{-3}\) in Japan, to 18–250 ng m\(^{-3}\) in Hawaii.(7)

Mercury is emitted into the environment by both natural and anthropogenic (human) processes. Input into the atmosphere occurs by degassing of the earth’s crust, emissions from volcanoes, soil erosion, as well as from anthropogenic sources. Most mercury in the atmosphere is elemental mercury vapor. Anthropogenic activities that have contributed to emissions include burning
mercury-containing fuels and materials, and industrial processes. Fossil-fuel coal and lignite contain mercury, often at levels $\geq 100$ ppb.\textsuperscript{6} The largest contributions to mercury emission from human activities include coal-burning electrical utilities, municipal waste combusters, commercial and industrial boilers, medical waste incinerators, and chlor-alkali plants.\textsuperscript{13}

### 3.2 Technical Uses

Historically, mercury has been used extensively (and still is to a lesser degree) in the extraction of precious metals (for example, gold and silver) as amalgams. The major use of mercury is in electrolytic cells (as the cathode) for the production of NaOH and Cl$_2$. Metallic mercury is used as a liquid contact material for electrical switches, in vacuum technology in diffusion pumps, thermometers, barometers, tachometers and thermostats, and in mercury-vapor lamps. Mercury is widely used in batteries. The standard calomel (Hg$_2$Cl$_2$) electrode, is used as the reference electrode for measurements of potentials in analytical electrochemistry. Mercuric oxide (HgO) has been used in antifouling paint for ships.

Mercury has been used in medicines, cosmetics, and in dentistry as silver amalgams for tooth restorations. Mercury chloride has been used in eye drops for newborns, for syphilis prophylaxis. Although banned in many parts of the world, mercury iodide (3\%) or mercury amidochloride (10\%) are used as skin-lightening creams and soaps by dark-skinned people.\textsuperscript{9}

Organic mercury compounds have been used as pesticides, particularly fungicides. Mercury compounds used in this capacity include aryl mercurics such as phenyl mercuric dimethylthiocarbamate, which was used as a slimeicide and mold-retardant in the paper/pulp industry, and alkyl mercurics such as ethylmercuric chloride (C$_2$H$_5$HgCl) which is used as a seed fungicide. Organic mercury compounds are also used for their germicidal properties, for example phenyl mercuric acetate.

### 4 SAMPLE PREPARATION

#### 4.1 Collection and Storage

Collection and storage are a critical part of any analysis for metals in environmental samples. Questions about trace-metal preservation and storage have resurfaced periodically over the years. These concerns stem from the health risk associated with certain metals, as the requirements for detection limits continue to lower. Because the mercury analytical technique is sensitive, great care in sampling protocols should be used. All sampling, storage and manipulation devices should be mercury free. Because of the risk of mercury in some laboratory environments, all laboratory equipment and sample collection tools should be stored in a clean mercury-free environment. Typical glassware/plasticware cleaning protocols include routine laboratory washing, rinsing with clean (mercury free) water, an acidic rinse and further rinsing with laboratory-grade clean (mercury free) water. The acidic rinses may be 1 + 1 nitric acid, 1 + 1 hydrochloric acid or aqua regia (three parts concentrated hydrochloric acid and one part concentrated nitric acid). Rinse times reported are for 12–24 h at room temperature, whereas some reports recommend rinsing at 70$^\circ$C for 24 h.

The type of analysis and matrix will dictate the sample collection, storage, and preservation protocols. For determination of mercury in waters the specific matrix may be: dissolved, suspended, total, or acid-dissoluble mercury, and this will dictate the type of collection protocol. Dissolved mercury analysis requires prefiltering samples prior to preserving. Filtration is typically through a 0.45-µm membrane filter. Preservation of other aqueous samples is typically with nitric acid (HNO$_3$) to pH < 2.0. The quality of nitric acid or other preservation chemicals should match the quality and precision of the analysis.

Unpreserved or acid-preserved mercury water samples may be collected in quartz, Teflon\textsuperscript{6}, linear polyethylene, or borosilicate glass to prevent loss of mercury through disproportionation and volatilization. Polypropylene containers were found to be unsatisfactory unless the preservation included concentrated hydrochloric acid, reportedly to form the soluble HgCl$_2^{2-}$ complex.\textsuperscript{10} Mercury concentrations may increase in samples stored in plastic bottles in mercury-contaminated laboratories; therefore, borosilicate or quartz is recommended for precise work. Glassware used in analyses where mercury is used as a reagent should be avoided (for example total Kjeldahl nitrogen (TKN), chloride or chemical oxygen demand (COD) procedures). Dedicated glassware for mercury-only analysis is ideal.

After acidification, it is recommended that samples be stored at 4$^\circ$C to minimize evaporation. Under these conditions, mercury is reported to be stable for only 5 weeks.\textsuperscript{11} For longer-term storage of mercury, other procedures have been proposed, such as 5.0% HNO$_3$ and 0.05% K$_2$Cr$_2$O$_7$ – for example, 2 mL L$^{-1}$ of 20% (w/v) K$_2$Cr$_2$O$_7$ in 1 + 1 HNO$_3$ has been recommended.\textsuperscript{12} This preservation procedure for mercury has been reported to be stable for up to 6 months in glass or 30 days in polyethylene containers.\textsuperscript{10}

Although soil, sediments, and plant tissue samples may be analyzed without drying, most work is reported on a dry-weight basis. Moisture may be driven off in a drying oven at 60$^\circ$C. No mercury losses have been observed
by using this drying step.\(^{(3)}\) The dry sample may be pulverized and thoroughly mixed before the aliquot is weighed. Samples should be stored in a dry, mercury-free environment until analysis.

Clinical sample collection and preservation include urine collected in glass or plasticware and preserved with glacial acetic acid or 1.5% nitric acid.\(^{(9)}\) Blood samples are collected as blood–EDTA (ethylenediaminetetraacetic acid). Recommended storage is at 4 °C until analysis; samples should be analyzed as soon as possible. For tissue samples immediate freezing is recommended.\(^{(13)}\)

### 4.2 Sample Pretreatment

Several authors recommend preparing mercury standard working solutions with about 2 µg L\(^{-1}\) potassium dichromate (K\(_2\)Cr\(_2\)O\(_7\)) for enhanced stability.\(^{(14,15)}\) However, others have noted at high concentrations, 0.34 mM, that a 5% loss of sensitivity was seen after 24 h.\(^{(16)}\) This pretreatment has also been recommended for sample preservation as discussed above.

### 4.3 Preparation of Environmental Samples

Most matrices require digestion of some type to free mercury from the inorganic and organic forms contained in the sample. Preparation/digestion methods for mercury analysis is still an active area of research.\(^{(17,18)}\) However, two sample types which may be analyzed directly include clinical aqueous samples, such as urine, and environmental aqueous samples where the DQO (data quality objective) is for dissolved mercury only. All other matrices require decomposition, typically by wet oxidation mineralization (section 5.6 discusses other digestions). The organic and inorganic matrix must be decomposed (digested) and all mercury present must be converted (oxidized) to mercury(II) prior to the cold vapor process. The oxidized mercury is then reduced to elemental metallic mercury vapor by one of the cold vapor techniques (section 5.1).

The digestion methods (decomposition) may be generalized in that each approach uses a strong acid or combination of acids, such as nitric acid, hydrochloric acid, perchloric acid and/or sulfuric acid, generally in combination with an oxidant such as hydrogen peroxide, potassium permanganate, potassium dichromate, potassium persulfate, or vanadium oxide. The function of the acid(s) is to decompose the inorganic and organic matter of the biological matrix. A host of processes/mechanisms are needed to represent the whole decomposition of solids and/or organic matter; details of these processes are not present here, but an excellent review is available.\(^{(17)}\) Briefly, most wet oxidation processes that involve organic matter are oxidative-hydrolytic processes. The samples are then typically treated with an oxidant. The purpose of the oxidant is to oxidize any organically bound mercury together with any unoxidized organic matter. In this way mercury is ensured to be in the soluble (nonvolatile) free form of Hg\(_{\text{II}}\). The use of the oxidant potassium permanganate is described in Equation (1):

\[
\text{MnO}_4^- + (\text{inorganic or organic}) \rightarrow \text{Hg} \\
\longrightarrow \text{MnO}_2 + \text{Hg}^{2+} + \text{CO}_2 + \text{inorganic salts} \quad (1)
\]

Potassium chromate may be used in a similar fashion—samples may be preserved with an oxidant such as chromate to ensure that mercury remains as Hg\(^{2+}\). Equation (2) illustrates how chromium(IV) prevents the loss of mercury through volatilization, by preventing the formation of Hg\(^{0}\).

\[
\begin{align*}
\text{2CrO}_4^{2-} + 16\text{H}^+ + 3\text{Hg} & \longrightarrow 2\text{Cr}^{3+} + 3\text{Hg}^{2+} + 8\text{H}_2\text{O} \\
(2)
\end{align*}
\]

Potassium permanganate oxidizes many of these compounds, but some studies have indicated that a number of organic mercurials, including phenyl mercuric acetate and methyl mercuric chloride, are only partially oxidized by this reagent.\(^{(5)}\) However, other studies have reported good recoveries of phenyl mercuric acetate using potassium permanganate.\(^{(14)}\) Potassium persulfate has been reported to give good recoveries when used as the oxidant with these compounds.\(^{(3)}\)

The digestions are routinely done at modest temperatures below 95 °C, due to the possible loss of mercury at elevated temperatures; for example, the bp of dimethylmercury is 96 °C. The exception to this is if closed-vessel digestions are used, such as microwave closed-vessel techniques or other sealed vessels such as Teflon\(^{19}\)- or quartz-lined bombs, where losses of mercury are minimized.

Excess oxidant (e.g. hydrogen peroxide, potassium permanganate, potassium dichromate, potassium persulfate, or vanadium oxide) must be removed prior to the cold vapor chemistry. Excess oxidant will interfere (consume) the reducing reagent(s) in the cold vapor chemistry process, potentially leaving insufficient reagent for the mercury chemistry. The addition of reagents such as oxalic acid,\(^{(14)}\) or hydroxylamine hydrochloride\(^{(19)}\) reduces excess oxidant such as permanganate without reducing the mercury. Oxalic acid is added to reach the final end-point, which is a colorless solution (i.e. Mn\(^{2+}\) is colorless, MnO\(_4^-\) is purple, and MnO\(_2\) is a brown precipitate;\(^{(17)}\) Equation (3):

\[
\text{MnO}_4^- + \text{H}_2\text{C}_2\text{O}_4 + 2\text{H}^+ \longrightarrow \text{Mn}^{2+} + 2\text{CO}_2 + 2\text{H}_2\text{O} \\
(3)
\]
Oxalic acid does not react with the mercury, leaving it as nonvolatile mercury(II). This mild reduction should be performed immediately prior to the cold vapor process.

A typical digestion procedure might be described as follows: take 1 g of biological material, add 3 mL of concentrated nitric acid to a 10 mL digestion test tube, heat to 95°C for 12 h, cool and treat dropwise with a saturated solution of potassium permanganate until the solutions remains purple (MnO₄⁻) or a brown precipitate persists (MnO₂), heat to 95°C for 10 min. Add oxalic acid to remove excess oxidant. Dilute to final volume and analyze by CVAAS (cold vapor atomic absorption spectrometry).

### 4.3.1 Clinical

Most techniques for the determination of mercury in solid matrices require a multistep approach. First, the conversion of all bound mercury in the sample to mercury(II) by a wet oxidation procedure (mineralization) and, second, the reduction of mercury(II) to mercury(0) vapor for analysis (discussed in section 5.1). If mineralization is required, the volatile nature of mercury should be kept in mind. There are numerous approaches to the digestion of clinical samples, as discussed above. Research on the determination of mercury in clinical and biological matrices has been extremely active over the last decade.

Most recently, the analysis of liquid clinical samples such as urine and blood have been analyzed directly, without pretreatment. Blood samples analyzed directly often require the addition of an antifoaming agent (e.g. octanol) to the cold vapor reagents. Numerous publications discuss the determination of mercury in biological matrices using several reagent combinations and equipment. These include microwave digestions and various combinations of acidic wet decomposition. Solid biological matrices are digested with acid, often with an oxidant.

Hair samples are often pretreated with an acetone washing prior to digestion. The acetone removes dust and oils from the hair matrix, but otherwise the samples may be treated like other biological solid matrices.

### 4.3.2 Agricultural

Methods applicable to biological tissues are often validated with agricultural plant matrices. Agricultural materials have been digested by a host of techniques, such as nitric–sulfuric acids with vanadium oxide. Potassium permanganate is a favored oxidant for biological and agricultural matrices (including soils). Closed-vessel digestions are gaining popularity for digesting agricultural matrices (plant material, soils and biological material) as microwave digestion ovens become more common in analytical laboratories.

### 4.2.3 Waters

Depending on the DQO, the water sample type may be dissolved, suspended, total, or total recoverable. For dissolved mercury the samples are filtered prior to preservation, with a 0.45 µm filter. Suspended mercury is the sample left on the filter. Total mercury is the complete digestion of the entire original sample, and total recoverable is a caveat that some digestion techniques have yet to demonstrate recoveries from all forms of mercury. Digestion of water matrices may proceed as outlined above; increased sensitivity may be achieved by using larger samples.

### 5 ANALYTICAL METHODOLOGY

#### 5.1 Cold Vapor Technique

Mercury is the only element that exists in metallic form at ambient conditions and at the same time exhibits a considerable vapor pressure. These unique properties enable unique methods of detection to be exploited. In addition, the traditional techniques, such as flame AAS, AFS, or ICPAES, exhibit poor mercury sensitivity. As mercury has a high vapor pressure (0.16 Pa at 20°C), mercury may be determined by AAS without the use of an atomizer. Mercury must be simply reduced to metallic mercury from its compounds and transferred as the vapor phase. This is accomplished by a chemical reduction reaction used to generate the gaseous mercury species.

There are two primary advantages of the cold vapor process. First, the mercury analyte is removed from the sample matrix, which reduces the potential for matrix interferences. Second, the detection limits are improved because all of the mercury sample is introduced into the atomizer (or nebulizer in the case of ICPAES) within a few seconds. Therefore, the density of mercury in the cell during data collection (absorption, fluorescence, or emission, depending on the detection technique) is greatly enhanced as compared to typical sample introduction.

The two reducing agents used exclusively for cold vapor analysis are tin(II) and sodium borohydride. Tin(II) chloride (SnCl₂) was used in most early applications of mercury cold vapor analysis; more recently sodium borohydride (NaBH₄; the correct nomenclature is sodium tetrahydridoborate) has gained some favor. Tin(II) chloride reacts with mercury as described by Equation (4):

\[
\text{Sn}^{2+} + \text{Hg}^{2+} \rightarrow \text{Sn}^{4+} + \text{Hg}^{0} \tag{4}
\]

The tin chloride technique requires that the metallic mercury be transported by an inert gas stream (for example argon or nitrogen) bubbled (purged) through the solution to drive out the mercury to the absorption
cell. Later applications use tin sulfate (stannous sulfate) instead of tin(II) chloride.\textsuperscript{[29,30]}

Sodium borohydride in an alkaline solution is becoming the preferred reagent; it requires no other reagents for the reduction. Sodium borohydride is a stronger reducing agent than tin(II) chloride. In addition, sodium borohydride produces dihydrogen as part of the reduction chemical reaction. The hydrogen can therefore transport the majority of the metallic mercury from the solution into the absorption cell. The sample digestate is acidic from the mineralization process (Equation 5):

$$\text{BH}_4^- + H^+ + 3\text{H}_2\text{O} \rightarrow \text{H}_3\text{BO}_3 + 8\text{H}^+ + \text{Hg}^{2+}$$
$$\rightarrow \text{Hg}_0 + 4\text{H}_2$$  \hspace{1cm} (5)

Sodium borohydride, which is prepared in basic media (e.g. NaOH) for stabilization purposes, should be prepared daily. Because of the production of hydrogen, the borohydride technique is limited to open systems.

5.2 Instrumental Developments

The cold vapor method for mercury has been described for several instruments, including AAS (most favored), AFS, and ICPAES. The earliest report of using mercury vapor, to monitor mercury in air, was in 1939 by Woodson.\textsuperscript{[31]} Later the use of Sn\textsuperscript{II} to produce mercury vapor was reported by Kimura and Miller,\textsuperscript{[32]} and this approach was subsequently optimized by Poluektov et al.\textsuperscript{[33]} One of the early descriptions of CVAAS for the analysis of mercury in environmental samples, soil and rock, was by Hatch and Ott in 1968.\textsuperscript{[34]} Cold vapor generators of numerous special designs have subsequently been described in the literature.\textsuperscript{[35]}

Overall, the CVAAS technique may be categorized as batch or flow systems. The AAS procedure is a physical method based on the absorption of radiation at 253.7 nm by mercury vapor. The mercury is reduced to the elemental state by the cold vapor process and aerated from solution. All of the mercury in the sample solution placed in the reaction vessel is chemically atomized and transported to the sample cell for measurement. The mercury vapor passes through a cell positioned in the light path of an atomic absorption spectrophotometer. Absorbance (peak height) is measured as a function of mercury concentration.

In the batch mode, specific volumes of sample and reductant are mixed at the start of the process, which culminates in the generation of a transient absorbance signal. A typical batch system for cold vapor generation is shown in Figure 1. The advantages of a batch system are that large volumes may be used, which increase sensitivity; sample volumes of 50 mL are routinely reported. The disadvantages include large reagent consumption, large dead volume, and the method is relatively slow and labor intensive.

In the flow injection system reagents are continuously pumped, the sample is injected into the carrier flow, and the flow then ultimately goes through a reaction (mixing) coil and a gas–liquid separator, thereby generating a transient absorption signal. In a continuous flow system the reagent and sample are continuously pumped, and the system flow proceeds as described above for flow injection. As the sample and reagents are continuously pumped through the system, this technique generates a continuous, flame-like absorbance signal. A typical continuous flow system for cold vapor generation is shown schematically in Figure 2. The advantages of a flow injection system are that smaller sample volumes are used, with consequent lower reagent consumption. The continuous and flow injection techniques are easily automated. Dead volume is reduced, which results in greater absolute sensitivities. Overall, the batch and flow techniques have similar absolute sensitivities, although batch systems use larger sample volumes to achieve the same sensitivity. Both systems have unique attributes and their suitability will depend on the application.

Any atomic absorption unit having an open sample presentation area capable of mounting an absorption cell is suitable. Instrument operating parameters are set according to the manufacturer. Instruments designed
specifically for the measurement of mercury using the cold vapor technique are commercially available and may be substituted for the atomic absorption spectrophotometer. Standard spectrophotometer cells 10 cm long and having quartz end windows may be used; alternatively, suitable cells may be constructed from plexiglass tubing.

Cold vapor for AFS works on the same principles as for AAS. The increase in sensitivity is a function of the selectivity of introducing mercury vapor into the instrument detection system, while eliminating most of the rest of the matrix constituents through the liquid waste. A CVAFS (cold vapor atomic fluorescence spectrometry) system consists of a vapor generator, mercury fluorescence detector, and measurement/computer system. The mercury vapor is removed in a gas–liquid separator by an inert gas (e.g. argon), the mercury is piped through a chimney past a light source and photomultiplier that are at right angles to each other. As the vapor absorbs the mercury light, it fluoresces at the same wavelength (typically 254.7 nm). The design allows for the efficient isolation of the required excitation and emission wavelength for sensitive quantitation of mercury. Numerous cold vapor techniques have proven satisfactory for this technique. Instrument operating parameters are set according to each particular manufacturer. Mercury sensitivities of 4–10 ng g⁻¹ have been reported.

Cold vapor may also be used in ICPAES applications, i.e. CVICPAES (cold vapor inductively coupled plasma atomic emission spectrometry). Mercury(II) is reduced by sodium borohydride in a continuous manifold. A standard pneumatic nebulizer effects the gas–liquid separation of mercury and concentrates the mercury into a small plug of gas, which is carried to the plasma. A cold vapor flow system for ICPAES is shown in Figure 3. This also provides longer residence time in the plasma, which further increases sensitivity. The introduction of volatile mercury increases the sensitivity by over 1000-fold as compared to liquid sample introduction for ICPAES analysis. This increase is because the transport efficiency of the gaseous mercury to the plasma is higher. In addition, atomization and excitation of the gaseous mercury is very efficient because the process avoids the energy-consuming desolvation and vaporization phases associated with liquid samples. Matrix effects are also minimized as most of the other constituents in the samples are in the liquid fraction and are directed past the sample introduction system in the ICPAES and into the waste stream. Instrument operating parameters are set according to each particular manufacturer. Mercury is quantitated by ICPAES at 194.232 nm. The sensitivity is reported to be 0.2 µg L⁻¹. Gas–liquid separators for ICPAES are commonly used and are available from many manufacturers; they may be used with either tin(II) or sodium borohydride. These same gas–liquid separators are also used for hydride generation for ICPAES.

5.3 Amalgamation
As the need for lower and lower detection limits is required by the analytical community, further enhancement of the cold vapor technique has continued to evolve. Again, capitalizing on the unique properties of mercury affords yet another development in the enrichment of the cold vapor technique. Mercury readily forms amalgamations with precious metals. With this technique, mercury is reduced to Hg⁰ vapor and transported by an inert gas (for example argon) in the typical manner used in the cold vapor technique. In this application, the mercury vapor is passed through an absorber, for example a gold gauze, where it is retained (Figure 4). In this way, mercury may be collected from large sample volumes or over extended periods, or both, thereby permitting high preconcentration factors. The mercury is subsequently released by rapidly heating the absorber to about 600 °C and mercury is determined in the typical manner. Detection limits of 3 ng L⁻¹ have been reported.

![Figure 3](image1.png)

**Figure 4** Batch mercury cold vapor generator with drying agent and gold amalgamation preconcentration.
and iodide are the only elements that have appreciable other metals which may be present in the matrix. Selenium not a strong reductant; therefore, it does not reduce many material, which can retain mercury. Tin(II) chloride is dride. Metals that can be reduced form fine particulate 5.4 Detection Limits

Detection limits depend in some measure on the matrix to be analyzed. The matrix may also dictate the type of analytical approach, together with the sensitivity requirements (Table 1).

5.5 Interferences

The most frequent source of error in the determination of mercury is typically the digestion which either does not break down the organomercury compounds or does not convert all of the mercury to the proper oxidation states. The other major source of error is mercury contamination from the laboratory environment. Typically, spectral and chemical interferences are of minor consequence in comparison. One of the primary advantages of the cold vapor process is that the analyte (mercury) is removed from the sample matrix, which reduces the potential for interferences. The matrix constituents are normally left in the reaction vessel. Therefore, due to the small number of constituents in the gas phase in the atomizer (nebulizer) spectral interferences are virtually excluded. Possible interference from water vapor was thought to interfere with the absorption at 253 nm in AAS analyses; this was later determined not to be a spectral interference. The water interference was due to droplets of solution, which were carried by the gas stream and subsequent condensation of the vapor in the absorption cell, reducing signal intensity. The water interference can be eliminated by either using a suitable drying agent or by warming the AAS absorption cell.

Fortunately, chemical interferences are nearly excluded for the two most common techniques used in the mercury cold vapor generation, namely SnII and sodium borohydride. Metals that can be reduced form fine particulate material, which can retain mercury, Tin(II) chloride is not a strong reductant; therefore, it does not reduce many other metals which may be present in the matrix. Selenium and iodide are the only elements that have appreciable effects on the SnII reaction. Sodium borohydride is a strong reductant; copper, and nickel, may form particulates which can retain mercury. The concentrations in most typical environmental matrices, which are required of these elements to interfere, seldom exceed the range of interference-free determination. Hazardous waste or other matrices with unique or high concentrations of these trace elements should be evaluated individually for potential interferences.

The hydride-forming elements may cause interference in the gas phase; SnII is a weak reductant and therefore represents a minor source of error. Sodium borohydride easily forms hydrides (with As, Se, etc.) and therefore can represent a large source of error, depending on the concentration of these hydride-forming elements.

Sodium borohydride also may reduce metals such as gold, silver, palladium, and platinum; mercury can form amalgams with these metals, thereby causing a suppression of the mercury signal. It has been shown that increasing acid concentration in the sample solution reduces interference from these metals. It has also been shown that the flow injection AAS system is less susceptible to interferences of this type. These types of interference are caused by the reduced form of the interferent, because the reduction takes some finite time; if flow conditions are optimized the mercury vapor reaches the absorption cell before significant amounts of interferent are precipitated and retain mercury (a kind of kinetic discrimination).

Nitric acid digestions used with sodium borohydride as the reducing agent in a flow injection AAS can cause poor reproducibility for mercury determination. It has been reported that the interference was due to inhibition of the mercury reduction by the volatile nitrogen oxides which were scavenging the reducing agent. This interference can be overcome by purging the sample with an inert gas (e.g. argon).

Seawaters, brines and industrial effluents high in chlorides require additional permanganate. During the oxidation step, chlorides are converted to free chlorine, which will also absorb radiation at 253 nm. This causes an enhancement of the signal. Care must be taken to ensure that free chlorine is absent before the mercury is reduced and swept into the cell. This may be accomplished by using an excess of hydroxylamine sulfate reagent. Alternatively, a sulfuric acid/dichromate digestion has been used successfully on high-chloride-content matrices.

Other reports ascribe the interference of chlorine on the mercury cold vapor technique to the re-oxidation of elemental mercury by chlorine inside the reduction–aeration system, causing suppression of mercury recovery. Non-chemical removal of the chlorine interference has been accomplished by the use of an additional heating step after digestions, which allows evaporation of chlorine yet retains mercury in the sample solution.

Report on CVICPAES analyses indicate no chemical interference for sodium, calcium, potassium, magnesium, chromium, manganese, iron, cobalt, nickel, copper, aluminum or zinc at 0.4%. Copper at or above 1000 µg g⁻¹.
did interfere with the mercury emission signal.\textsuperscript{(14)}铜 was observed to be plating out on the tubing.

Possible interference from sulfide is eliminated by the addition of potassium permanganate. Concentrations as high as 20 mg L\textsuperscript{-1} of sulfide as sodium sulfide do not interfere with the recovery of added inorganic mercury from distilled water.\textsuperscript{(3)}

5.6 Speciation

Speciation of mercury is meaningful because of the toxicity of certain mercury compounds, and the importance of understanding the movement, bioaccumulation, and transformations of mercury. Methylation of mercury is the critical reaction in the entry of mercury into the food chain. Biotransformation of inorganic mercury species to methylated organic mercury species occurs in the sediment and water column. However, not all inorganic mercury is converted to methylmercury; reactions such as demethylation and volatilization also occur.\textsuperscript{(3)} The rates of these reactions are not well understood. All forms of mercury accumulate to some degree in organisms, but methylmercury accumulates to a much greater extent. In addition, elimination of methylmercury by organisms (e.g. fish-eating birds, fish, and humans) is slow compared to inorganic forms of mercury. The toxicological risks of methyl mercury compounds are therefore more significant.

Speciation of mercury is a relevant analytical goal because, as yet, no single method permits unequivocal identification of all mercury species. More often, broad classes of mercury such as “inorganic mercury” and “organic mercury” are commonly reported. One of the early works on mercury speciation was based on the preparation of a biological sample using alkaline digestion\textsuperscript{(41,42)} often referred to as the Magos method. The method depends in part on the reaction rate kinetics for conversion of methylmercury by the reductant to be slow compared to the analytical process. The sample preparation is based on alkaline digestion with NaOH and cysteine. Briefly, about 1 g of sample is solubilized in 10 mL of 1:1:1 1% NaCl, 45% NaOH and 1% cysteine at 80°C.\textsuperscript{(43)} The cysteine is thought to complex with mercury and minimizes mercury volatility.\textsuperscript{(44)} The high-pH sample is then reduced with the addition of tin(II) to form metallic mercury vapor as described in Equation (4); the sample is then analyzed in typical fashion by AAS. The mercury determined in this manner is termed inorganic mercury. Total mercury is analyzed by the same procedure, but a Sn–Cd reductant is used which reduces inorganic and organic mercury to metallic mercury vapor. Organic mercury is estimated as the difference between total and inorganic mercury. Current reports indicate that this technique overestimates the concentration of inorganic mercury in the presence of methylmercury.\textsuperscript{(43)} Degradation of methylmercury during the formation of the analytical signal is thought to account for the overestimate.\textsuperscript{(45)} Similar approaches, such as staging digestions, have been used with some success.

Most recent reports depend on hyphenated methods for speciation\textsuperscript{(45,46)} such as liquid chromatography (LC)/ICPMS, (inductively coupled plasma mass spectrometry)\textsuperscript{(47)} electrothermal (ET)/ICPMS,\textsuperscript{(48)} and gas chromatography (GC)/CVAFS.\textsuperscript{(49)} Other speciation methods include physical/mechanical separation (separation based on molecular size), and potentiometric methods (separation based on differences in electrical potential).

6 ENVIRONMENTAL REGULATIONS

Concentrations of mercury in air and water are typically low, and pose little health risk. However, once mercury enters water, either directly or through air deposition, it can bioaccumulate in fish and animal tissue as methylmercury. Human exposure to mercury occurs primarily through eating contaminated fish. Exposure to high levels of mercury has been associated with serious neurological and developmental effects in humans.\textsuperscript{(3)}

Table 2 lists some examples of environmental mercury standards, including some drinking water limits from various agencies and countries. Because of the diverse mechanisms by which mercury may be introduced into the environment, mercury regulations often span several agencies. The USEPA regulates mercury in pesticides and mercury releases into the environment (air, water, and land disposal), the FDA regulates mercury in

food, cosmetics and dental products, and the USOSHA regulates mercury in air exposure in the workplace.

The USEPA program for water, Contract Laboratory Program (CLP), and the Resource Conservation and Recovery Act (RCRA) accept results from several different digestions/instruments. A summary of USEPA methods for the determination of mercury is given in Table 3.

7 QUALITY CONTROL AND TROUBLESHOOTING

7.1 Data Quality Objectives

The DQOs are typically project defined. Spikes and check standards will typically have >95% recovery. Concentrations close to the detection limit will have inherently more variability. Typically, recoveries of SRMs (standard reference materials) are reported at >85% for total mercury. Speciation of mercury is currently not reported to be nearly as accurate, with some species of mercury recovered at <85%. Speciation of mercury is still an active research area.

7.2 Instrument Performance

A good, general preventive maintenance program will keep equipment in top performance longer and therefore is highly recommended. A review of troubleshooting is beyond the scope of this article and has been covered elsewhere. Briefly, in the case of erroneously low results or no signal, cold vapor reagents should be checked to ensure they are mixing and have not deteriorated; other items to check are gas lines, contamination of blank, and matrix interferences. In the case of erroneously high results, check that blank correction was performed properly and that standards have not deteriorated, also check for memory effects and matrix interferences.

7.3 Standard Reference Materials

A minimum number of quality control (QC) samples should be analyzed as part of the QC program defined by the DQOs, as follows. Laboratory blanks prepared with the samples are a matrix blank, used to cancel interference or contamination from reagents or analytical manipulations and should be included in the analytical batch. Laboratory spikes should be analyzed for. An example would be to prepare by spiking a sample with 50 ng mL⁻¹ of 1 µg L⁻¹ mercury solution and calculating the percentage recovery; other concentrations may be more appropriate depending on the specific application. If the recovery falls within 85–115%, the analysis has passed QC; the recovery window is defined by the project DQOs. SRM should be included in the analytical batch. Depending on the matrix, the best possible similar SRM should be included. Examples are: NIST (National Institute of Standards and Technology), oyster tissue, NIST pine needles, NIST bovine liver, and NIST citrus leaves (for biological matrices); NIST Buffalo River sediment, National Research Council of Canada (NRC) estuarine sediment, NRC harbour sediment, BCR (European Commission, Belgium) river sediment, BCR light sandy soil, BCR sewage sludge amended soil, BCR sewage sludge of domestic origin (for soils, sludge, and sediment matrices). For aqueous environment samples NIST, NRC, BCR, or other vendor’s trace-metal SRMs should be included. The SRM should have mercury levels within the concentration ranges that are expected in the samples to be analyzed. In-house SRM may be substituted if a sufficient confidence level can be demonstrated with the mercury concentration. The frequency of the QC samples depends on the project DQOs; 10% of each QC type is often used as a default frequency; SRMs for the speciation of mercury are currently inadequate/unavailable.

8 METHOD COMPARISON

8.1 Instrumental Technique Comparison

Detection limits depend in some measure on the matrix to be analyzed. In addition, the matrix dictates the type of analytical technique approach, in addition to sensitivity requirements. Detection limits using the cold-vapor process for detection of mercury are given in Table 1. Instrument detection limits for non-cold-vapor techniques are given in Table 4.

8.2 Other Techniques

There are numerous approaches to mercury analysis and some techniques require fairly specialized equipment. Mercury in environmental matrices has been routinely determined by several techniques,\(^{[13]}\) including CVAAS, ETAAS,\(^{[53]}\) AFS,\(^{[54,55]}\) CVICPAES,\(^{[14]}\) GC/MS,\(^{[56]}\) ICPMS,\(^{[52,57–59]}\) and NAA.\(^{[60,61]}\) Examples of some selected mercury methods specifically for water and environmental aqueous solutions include LC/ICP/MS (liquid chromatography/inductively coupled plasma/mass spectrometry),\(^{[62,63]}\) X-ray fluorescence (XRF),\(^{[64]}\) and spectrophotometric techniques.

This report describes innovative methods for sample pretreatment in organic environmental analysis that involve the use of microwave-assisted techniques. The methods described include: microwave-assisted extraction (MAE), focused microwave-assisted Soxhlet extraction (FMASE), microwave-assisted headspace analysis, microwave-assisted derivatization (MAD), microwave-assisted saponification (MAS) and microwave-assisted decomposition. A brief history of the development of each technique is provided. Reference is made to literature published up to the beginning of 1999.

1 INTRODUCTION

Modern analytical instruments can offer extremely low detection limits with high precision, resolution, reproducibility and speed of operation. But most of these methods require quite extensive sample pretreatment due to the great complexity of analytes and matrices in environmental samples. This is usually the most time-consuming step in the whole analytical process. Therefore, the development of novel methods and techniques for sample pretreatment has attracted a great deal of attention from researchers. Since the mid-1980s a number of innovative pretreatment techniques have been introduced. These include: supercritical fluid extraction (SFE), solid-phase extraction (SPE), solid-phase microextraction (SPME), the supported liquid membrane (SLM) technique for extraction, accelerated solvent extraction (ASE) and high-performance capillary electrophoresis (HPCE). This report will outline other innovative methods for sample pretreatment in organic environmental analysis that involve the use of microwave-assisted techniques.

Interestingly enough, the first recorded uses of microwave ovens in chemical laboratories involved sample pretreatment in preparation for analysis. In 1974, Hesek and Wilson reported that a commercial microwave oven was employed to dry inorganic samples in process control, then subsequently Abu-Samra et al. reported the use of microwave energy for the wet ashing of some biological samples prior to determination of metals content. But the major breakthrough came with the development of microwave-assisted acidic pressure digestions and microwave-assisted chemical synthesis and the subsequent availability of cheap, microwave-transparent vessels able to withstand the rigorous conditions. Since then, this approach has been progressively established as a standard method for preparation of samples for elemental analysis.

Recently, microwave energy has been further employed to develop a four-stage sequential extraction method for metal fractionation in soil and sewage sludge samples. In the mid-1980s, Ganzler et al. pioneered the use of microwave energy for organic extractions in sample pretreatment. They used microwave radiation from a conventional household microwave oven to enhance the extraction of various types of organic compounds from soil, seeds, foods and feeds. This MAE method gave higher recoveries and proved environmentally friendly in yielding considerable savings in time, energy and solvent compared with the conventional methods. Moreover, MAE had the advantage of being admirably suited for the isolation of thermally labile substances due to the dramatic savings in extraction time. The advantages of MAE have led to its widespread acceptance by practicing analysts in this field.

In addition, a series of new microwave-assisted techniques, such as MAS, MAD and microwave-assisted decomposition have also been successfully developed in the last few years. These techniques can be separately employed for sample pretreatment in organic analysis or used in combination with MAE.

Details of the various microwave systems available and the theoretical basis of microwave heating are given elsewhere in this volume. Several useful reviews have appeared which put the various developments into perspective and demonstrate the wide applicability of microwave-assisted processes.\(^{13,14,22–27}\)

## 2 MICROWAVE-ASSISTED EXTRACTION

Of all the microwave-assisted techniques for sample pretreatment for organic environmental analysis, MAE is the longest-established, best-studied and most widely-used. In performing MAE, a number of important parameters must be controlled, including sample size, solvent (extractant) type and volume, microwave irradiation time, magnetron power output and the temperature of the extraction system. The pressure in the sample vessel is also important when a closed-vessel system is used for MAE. All the parameters can be optimized by chemometrics and factorial design. Generally, the duration of an MAE cycle is less than 30 min, of which microwave irradiation time is about 10 min, and the quantity of solvent needed is less than 50\% of that required for traditional Soxhlet extraction. The two principal microwave systems employed for MAE are the closed-vessel MAE system and the open focused microwave-assisted extraction (FMAE) system. For the FMAE both an open-vessel and a focused microwave unit are employed. There are some significant differences in experimental parameters and application areas between these two techniques.

MAE has been used in isolating a variety of analytes from a range of sample types. The increasing applications of this method are described in several review articles.\(^{13,15,23,28–34}\) The original work by Ganzler et al. involved isolating various types of organic compounds and biologically active compounds from seeds, foods, feeds and rat feces.\(^{18,35–37}\) This type of application of the process has been continued and expanded. In two patents held by Pare et al., the extraction of essential oils and other oils from biological materials such as plant and fish tissue,\(^ {38}\) and extraction of natural products from mint, garlic, etc.,\(^ {39}\) have been described. Prior to the issue of these patents, Craveiro et al.\(^ {40}\) also developed a method for the extraction of essential oils from fresh plant materials, which made use of MAE. In addition, the extraction of the essential oil components from rosemary leaves, including a study of the kinetics of the MAE process, has been reported by Chen and Spiro.\(^ {41}\) The extraction of antibodies from the surface of red blood cells was investigated by Torloni et al.\(^ {42}\) Banerjee et al.\(^ {43}\) have reported a microwave-based DNA extraction from paraffin-embedded tissue for polymerase chain reaction (PCR) amplification. Young\(^ {44}\) has used the technique for isolating the fungal metabolite ergosterol and total fatty acids. Leray et al.\(^ {45}\) reported an MAE method for isolating the fungal metabolite ergosterol from finished layers ration. Carro et al.\(^ {46}\) studied the extraction of monoterphol s from must samples, while Wang et al.\(^ {47}\) reported isolating Veltol\(^ {®}\) and Veltol-Plus\(^ {®}\) using MAE.

In addition to its applications in bioanalysis, food analysis and natural products extraction, MAE has also been used in isolating additives from polymers\(^ {34,49–51}\) and in the extraction of oligomers from poly(ethylene terephthalate) (PET).\(^ {52}\)

Probably the greatest number of reported applications of MAE involves sample preparation for organic environmental analysis. Examples include extracting polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), organophosphorus pesticides (OPPs), phenolic compounds, chlorinated benzenes, petroleum hydrocarbons, triazines, imidazolione herbicides, sulfonylurea herbicides, methylmercury and other organometallic compounds, from soils, sediments, sewage, air particles, plants, and tissue from marine mammals.\(^ {18,20,21,53–91}\) Polychlorinated dibenzo-\(p\)-dioxin (PCDD) and polychlorinated dibenzofuran (PCDF) were also extracted from solid samples such as fly ash, soil, wet sediment and sewage sludge.\(^ {58}\) The work of Lopez-Avila et al.\(^ {13,22,56,82,83}\) in evaluating the relative merits of MAE and the standard methods used by the United States Environmental Protection Agency (USEPA) for the extraction of the principal organic pollutants is worthy of note. Their research results demonstrate\(^ {55,56}\) that most of these compounds can be recovered in good yields from the soil/sediment samples that they studied using MAE. For example, they report recoveries of 80–120\% for 79 of the 95 compounds listed in USEPA Method 8250,\(^ {92}\) 38 of the 45 OCPs listed in Method 8081,\(^ {93}\) and 34 of the 47 OPPs listed in Method 8141A.\(^ {94}\) For 15 compounds in a reference soil, the recoveries of 14 compounds by MAE were equal to or better than recoveries obtained by Soxhlet extraction (naphthalene being the exception). For selected OCPs, recoveries from spiked soil samples were at least 7\% higher for MAE than for either Soxhlet or sonication extraction. Moreover, MAE also compared favourably with SFE.\(^ {95}\) In summary, it would appear that MAE can minimize pollution in the laboratory, improve target analyte recoveries and reduce sample preparation costs.

As well as being used for isolating organic analytes from diverse solid matrixes, MAE can also be applied to the
preparation of water samples. For example, microwave protocols for the extraction of PCBs and chlorinated benzenes from water samples have been developed by Onuska and Terry. The use of aqueous extractants is especially suited to microwave-assisted techniques, and several new methods have been reported. The MAE method has been used in combination with other extraction techniques such as SPE and SPME. The methods which use MAE in combination with MAD, saponification, saponification–derivatization, decomposition or saponification–decomposition, will be discussed in the appropriate sections of this article.

A selection of cited applications of MAE for sample preparation in organic environmental analysis is given in Table 1. Although several nonpolar or weakly polar solvents are listed as extraction media, it is essential that some moisture or polar solvent be present in the system to enable the absorption of the microwave energy.

DCM, dichloromethane.
3 FOCUSED MICROWAVE-ASSISTED SOXHLET EXTRACTION

One of the most recent applications of microwave energy for sample pretreatment in organic environmental analysis is FMASE, which has recently been described by Garcia-Ayuso et al. (95) The device itself consists of two main parts: the microwave irradiation zone, which includes a modified Prolabo Microdigest 301 (200 W maximum power) microwave source along with a modified Soxhlet extractor, and a distillation flask which is connected to a cooling unit. Two peristaltic pumps are used for solvent aspiration and siphoning in addition to the Soxhlet action. A special thermometer is used for monitoring the extraction temperature; three monitors control the microwave unit, pumps, and the thermometer. An electrical mantle is used as a heating source for the distillation flask.

The FMASE apparatus described above has been used to extract three different kinds of organic contaminants, namely alkanes, PAHs and herbicides, from clay soil. DCM was used as the extractant. For a 7-g sample, ultrapure water (1.0 mL or 1.5 mL) was added to the cartridge and the sample was allowed to soak for 10–15 min (water mainly acts to enhance the absorption of microwave energy). Then, the cartridge thimble was covered with a loose wad of glass wool and inserted into the extraction vessel, which was placed in the microwave irradiation zone. The extraction was performed as follows:

1. the extraction vessel was filled with 50 mL of fresh extractant delivered by pump 1;
2. the sample was subjected to microwave irradiation for 15 s at 50% of maximum power output;
3. the extraction vessel was drained by pump 2.

This extraction cycle was repeated a number of times depending on the target analytes. The duration of each cycle was 6 min, so a whole extraction program took 50–60 min.

The results of the study demonstrate that:

- FMASE provides efficiencies similar to those obtained by the conventional Soxhlet method with extraction times at least eight times shorter (50–60 min versus 8 h).
- FMASE can be used for almost all the applications of a conventional Soxhlet extraction under similar operating conditions.
- FMASE can be used for treating wet samples whereas the conventional Soxhlet method is usually suitable for dry samples only.

4 MICROWAVE-ASSISTED HEADSPACE ANALYSIS

The isolation and analysis of the volatile organic compounds (VOCs) in water samples may be carried out by transferring the volatile material in the headspace above the liquid surface to a gas chromatography (GC) device. Pare et al. have made use of microwave heating to improve the conventional headspace method. (96) The standard headspace sampler is still used to sample the vapor above the water and then to transfer the analytes into a GC device but the different method of heating gives very significant improvements in isolating efficiency.

The VOCs, namely benzene, methy1benzene, ethylbenzene, chlorobenzene, o-, m-, and p-xylene, and 1,2-, 1,3-, and 1,4-dichlorobenzene, were isolated from both spiked and actual samples at parts per trillion (ppt) to parts per million (ppm) levels. Compared with the conventional headspace method, this new technique offers enhanced sensitivity as evidenced by a 35% increase in signal strength and a dramatic reduction in the time required for the establishment of equilibrium (from 30 min to 1 min).

5 MICROWAVE-ASSISTED DERIVATIZATION

Since the first studies by Smith et al., (11,12) the use of microwave energy for the acceleration of organic reactions has increased enormously. (22,97) Recently, microwave-assisted esterification was used for the gas chromatography/mass spectrometry (GC/MS) determination of fatty acids in food oils. (98) The esterification of the fatty acids was carried out in methanolic 0.4 M KOH solution in a closed vessel with 30 s of microwave irradiation (600 W). Considerable savings of time and solvent were obtained with this method as compared with the conventional derivatization procedure.

Although derivatization reactions were among the first studied by the early researchers in this field, (99) the use of MAD for sample pretreatment in organic environmental analysis first appeared in a report by Lalere et al. (20) For the speciation analysis of organotin compounds in sediments by capillary GC with flame photometric detection (FPD), microwave-assisted ethylation of the organotin compounds was combined with MAE of the ethylated products. First, MAE of the target compounds from a sediment sample was performed with methanolic 0.5 M ethanoic acid as the extractant. Next, the separated supernatant solution was placed in a 50-mL reaction vessel and the derivatization reagent (sodium tetraethylborate, NaBEt₄), extractant (isooctane) and a certain volume of artificial seawater were added. Then the mixture was
exposed to a focused microwave field. The results showed that at volumes lower than 20 mL, quantitative recoveries were obtained with irradiation for 3 min at a microwave power of 70 W for all the compounds except monobutyltin (MBT), for which the recovery was close to 100% following a microwave irradiation for 10 min. The conventional process is also a multistage operation. The ethylation involves 30 min of magnetic stirring followed by extraction of the ethylation products. For the simultaneous extraction–derivatization reaction, the kinetics of the two processes were studied. Ethylation is a nucleophilic substitution, and the extraction is transfer of the derivatized analytes to the organic phase. It was demonstrated that the ethylation was apparently faster than the transfer process, and could be completed within 5 min if the reaction product was removed from the reaction medium or the phases were homogenized. Therefore, extraction does not affect derivatization in this case.

For the speciation analysis of organotin compounds in biomaterials, Pereiro et al. (103) developed an interesting microwave-assisted method by which sample decomposition, extraction, and derivatization of organotin compounds could be carried out simultaneously in a single reactor. Acetic acid was selected as the reaction medium, NaBEt₄ as the derivatization reagent, and nonane as the extractant. The reactions were conducted in a focused microwave field with 40 W power for 3 min to reach a temperature of 130 °C. It was found that ethyl derivatives of mono-, di-, and triorganotins were quantitatively detected in the supernatant organic phase. Furthermore, the new method was validated by analyzing a certified reference material (fish tissue, NIES11). The kinetics of simultaneous extraction–derivatization reaction were also investigated. Thus the hours-long multistep sample preparation procedure may be replaced by a one-step integrated method taking only 3 min.

Rodriguez et al. (103) also reported a speciation analysis of organotin compounds in marine biomaterials via microwave-assisted sample preparation using a closed-vessel microwave unit. Tetramethylammonium hydroxide was used as the reaction medium, and the pH of the reaction system was adjusted to 5. NaBEt₄ was used as the derivatization reagent, and isooctane as the extractant. This caused the simultaneous alkaline decomposition of the sample, the derivatization of the analytes (organotins) and extraction of the derivatization products. This study also included an investigation of the stability of organotin compounds on exposure to microwaves.

Llompart et al. (104) described in situ MAE and derivatization for sample preparation to determine phenol and methylphenol isomers in soils. The sample, to which small quantities of acetic anhydride and pyridine had been added in order to catalyse the acetylation process, was immersed in hexane in a closed vessel. Microwave irradiation parameters and other conditions concerning the method were optimized using a factorial design approach. Compared with ultrasonic extraction, the microwave-assisted method gave superior recoveries (about two-fold) and greater precision, in addition to shorter extraction times. The analytes extracted in the hexane phase could be directly analyzed on a GC/MS system without preliminary clean-up or concentration steps.

6 MICROWAVE-ASSISTED SAPONIFICATION AND MICROWAVE-ASSISTED DECOMPOSITION

There have been many applications of MAS or hydrolysis. Microwave energy was used by Chiou and Wang (105) for peptide and protein hydrolysis without significant degradation of the analytes. Tatar et al. (106) also described a microwave hydrolysis system to determine the amino acid composition of protein. Arai and Kakishita (107) reported the manufacture of soap from olive oil and the saponification of PhCO₂Me by microwave heating. Rapid acid hydrolyses of albumin (108) and benzodiazepines (109) were investigated by Morales-Rubio et al. Taketomi et al. (110) established a microwave-mediated saponification of galactosylceramide (cerobroside) and galactosylceramide 3-sulfate (sulfide) to prepare their lyso-compounds. Moreover, Perez and Haswell (111) developed a flow injection analysis (FIA) method with online MAS of vitamin A to retinol; Young (112) reported a simultaneous MAE and saponification to isolate the fungal metabolite ergosterol from various samples and the fatty acids from spores for their determination. Recently, Pineiro-Avila et al. (19) established a MAS of animal grease for cholesterol determination.

MAS also has applications in organic environmental analysis. Tseng et al. (89) developed a method to detect inorganic mercury and methylmercury in biological samples by MAS coupled with hydride generation, cryofocusing and atomic absorption spectroscopy (AAS) determination. Saponification was performed in tetramethylammonium hydroxide or methanolic KOH solution with microwave irradiation of 40–60 W for only 2–4 min, which was much faster than previously reported methods. This new method was validated by the analysis of four biological certified reference materials, CRM 463, DORM-1, TORT-1 and Tuna fish 2. Recently, Xiong et al. (21) reported a MAS of mussels for PCB determination using a closed-vessel microwave system. A 15-g sample in 30 mL of methanolic KOH solution could be completely saponified in less than 2 min without affecting the PCB analytes. For the speciation of
butyltin compounds in biomaterials, Szpunar et al.\textsuperscript{112} used saponification of the sample in tetramethylammonium hydroxide in a low-power microwave field. The biomaterial could be dissolved in less than 5 min, leaving the organotin moiety intact. In addition, as mentioned in section 5, MAS was also studied by Rodriguez et al.\textsuperscript{103} for the speciation of butyltin compounds in marine biomaterials. There have been several reports of the use of similar methods for the speciation of other organotin compounds.\textsuperscript{113–115}

It is important to distinguish between microwave-assisted decomposition and microwave-assisted digestion (wet ashing) for elemental analysis. In this article, microwave-assisted decomposition for organic environmental analysis refers to the selective decomposition of the sample matrix leaving the target analytes unchanged, whereas in microwave-assisted digestion (wet ashing) the whole sample is broken down.

When gas chromatography/electron capture detection (GC/ECD) is employed for determining PCBs in real-world samples, the co-existing OCPs, such as benzene hexachloride (BHC) and DDT (1,1,1-trichloro-2,2-bis\((p\)-chlorophenyl)ethane) often interfere with the determination of the target analytes. Xiong et al.\textsuperscript{116,117} have developed a microwave-assisted decomposition–extraction method for soil/sediment sample preparation and a MAS–decomposition–extraction method which addresses this problem. Methanolic 1 M KOH solution was selected as the reaction medium and the reaction conditions are optimized so that BHC, \(\text{o-p-DDT}\), \(\text{p-p-DDT}\) and \(\text{p-p-DDD}\) (1,1-dichloro-2,2-bis\((p\)-chlorophenyl)ethane) are completely decomposed after microwave heating for 2 min. Although dieldrin, aldrin and \(\text{p-p-DDE}\) (1,1-dichloro-2,2-bis\((p\)-chlorophenyl)ethylene) are only partly degraded under these conditions, most of their decomposition products and dieldrin itself can be eliminated with an additional rinse using concentrated \(\text{H}_2\text{SO}_4\).

In some publications,\textsuperscript{102,20} microwave-assisted acidic decomposition of biomaterial samples for the speciation of organometallic compounds is reported. Generally, acetic acid is chosen because, compared with hydrochloric acid, it has a higher boiling point, lower acidity (and thus better compatibility with derivatization–extraction) and neutral behavior towards the carbon–metal bond.\textsuperscript{102} According to these reports, microwave-assisted acidic decomposition, actually acidic hydrolysis, may be carried out rapidly and to completion.

### 7 CONCLUSIONS

For sample preparation in organic environmental analysis, a number of published reports have demonstrated that MAE possesses significant advantages over conventional methods such as Soxhlet and sonication extractions. These advantages include increased recoveries and great savings of time, energy and the quantity of organic solvents consumed. Compared with SFE, MAE generally also has a higher efficiency and wider field of application. Similarly, MAD, MAS, microwave-assisted decomposition, FMASE and microwave-assisted headspace analysis all show significant benefits over the earlier methods. Therefore, it can be predicted that in the near future, more and more laboratories will replace the conventional methods with these newly developed techniques, and they will become routine tools for sample preparation in organic environmental analysis.

However, there is still a need for further developments. In particular:

- microwave instruments, especially the closed vessel systems, need to be more adaptable to automation, making on-line preparation/determination for organic environmental analysis more readily achievable
- to minimize the use of organic solvents, further development of cheap, less toxic aqueous systems for microwave-assisted processes is required
- simultaneous application of several microwave-assisted techniques may further increase the selectivity for isolating target analytes
- the field of application for microwave-assisted techniques for sample preparation in organic environmental analysis may be greatly widened by using them in conjunction with other methods of sample preparation.

### ACKNOWLEDGMENTS

Guohua Xiong would like to thank Professor Zhanxia Zhang for providing guidance while he was studying for his Ph.D. at Zhongshen (Sun Yet-Sen) University, Guangzhou PR of China. His research related to this article was supported by the National Natural Science Fund of China (No. 29967001).

1 INTRODUCTION TO ENVIRONMENTAL ORGANIC SAMPLE PREPARATION

Analysis of organic pollutants in the environment is necessary because of past or present industrial activity, accidental spillage and deliberate (unlicensed) disposal, all of which can have ecotoxicological effects on living organisms. In order to assess the potential damage, remediate known sites or simply to have an early warning of potential problems requires environmental measurement of the levels of organic pollutants. Organic pollutants are located in all compartments of the environment. Thus, typically we refer to pollution in terms of natural waters (e.g. lakes, rivers, groundwater, potable water), solid or semisolid matrices (e.g. soil, sludge, vegetation) and the atmosphere (e.g. air). In this article we are concerned principally with solid-type matrices, although some attention is given to aqueous sample preparation. A recently published book discusses the different types of sample preparation approaches for both liquid and solid samples of environmental origin.\(^{(1)}\)

Preparation of solid samples for organic analysis can traditionally be subdivided into two classes, with heating and without heating. In the latter case, we refer to the use of a shake flask, while in the former Soxhlet extraction is used. Shake-flask extraction involves placing a solid sample into a container together with an organic solvent and agitating, either manually or by the use of a laboratory shaker, for a given period of time. Subsequently the organic solvent containing the extract is removed via filtration, a separating funnel or decanting. Soxhlet extraction involves refluxing warm organic solvent through the sample repeatedly for several hours. This is achieved by heating organic solvent contained in a round-bottomed flask, on an isomantle. The vaporized solvent is then condensed, via a water-cooled condenser, and falls into a thimble containing sample. This in turn returns to the round-bottomed flask. The whole process is repeated frequently until the preset extraction time is reached. As the extracted analyte will normally have a higher boiling point than the solvent it is preferentially retained in the flask and fresh solvent recirculates. This ensures that only fresh solvent is used to extract the analyte from the sample in the thimble. A disadvantage of this approach is that the organic solvent is below its boiling point when it passes through the sample contained in the thimble. In practice this is not

and xylenes (BTEX) from aqueous samples. Finally, some recommended operating conditions for the extraction of analytes from solid matrices using pressurized microwave-assisted extraction (MAE) are provided.
necessarily a problem as Soxhlet extraction is normally done over long time periods i.e. 6, 12, 18, or 24 h.

More recently, alternative approaches have become available. In addition to the shake-flask approach it is possible to agitate the sample using a sonic bath or sonic probe. Modifications of Soxhlet extraction have appeared which offer some degree of solvent reduction and automation, e.g. Soxtec. Perhaps the biggest changes have occurred in terms of the instrumentation available for extraction of pollutants from solids. The 1980s saw the arrival of commercial apparatus for supercritical-fluid extraction (SFE), while the early 1990s heralded the commercial availability of MAE closely followed in 1995 by accelerated solvent extraction (ASE).

This article is concerned with the use of microwave technology for the extraction of organic pollutants from environmental (solid and liquid) matrices. While the first papers on the subject were published in 1986, using a domestic microwave oven, this article only considers the work published in the 1990s when commercial systems became available.

2 PRINCIPLES OF MICROWAVE HEATING FOR ORGANIC SOLVENTS

Microwaves are high-frequency electromagnetic radiation. The most commonly used frequency of operation of microwaves is 2.45 GHz. The choice of solvent for MAE is essential. The solvent must be able to absorb microwave radiation and pass it on in the form of heat to other molecules in the system. The ability to pass on this energy is measured in terms of the dissipation factor (\( \tan \delta \)), see Equation (1):

\[
\tan \delta = \frac{\varepsilon''}{\varepsilon'}
\]

where, \( \varepsilon'' \) is the dielectric loss (a measure of the efficiency of conversion of microwave energy into heat energy) and \( \varepsilon' \) is the dielectric constant (a measure of the polarizability of a molecule in an electric field).

This polarizibility is achieved by the reorientation of permanent dipoles by the applied electric field. This means that under microwave conditions, a polarized molecule will rotate to align itself with the electric field at a rate of approximately \( 10^9 \) times per second. This results in very rapid heating. An estimate of the ability of the microwave oven to couple to any molecule can be obtained by considering its \( \varepsilon' \) values (Table 1). It is not suprising to find therefore that polar solvents, such as water, acetone and methanol all readily absorb microwaves and hence are heated up when subjected to microwave radiation, while nonpolar solvents, such as hexane and toluene, do not heat up when they are subjected to microwave irradiation. In addition, since the extraction process typically takes place in a closed vessel, the solvent chosen can be heated well above its normal boiling point (Table 1). This will reduce the time required for the extraction process.

3 APPARATUS FOR MICROWAVE-ENHANCED SOLVENT EXTRACTION

Two types of microwave heating systems are commercially available: an open-vessel (atmospheric) system and a closed-vessel (pressurized) system. In the open-style system, individual sample vessels are heated sequentially. A typical commercial system is the Soxwave from Prolabo Ltd., France. A schematic diagram of the atmospheric-MAE system is shown in Figure 1. This system operates at percentage power increments from 0–100%, corresponding to a maximum of 300 W. These power increments can be operated in stages and for various time intervals (up to 9 h). The sample and solvent are introduced into

a glass container which is fitted with either an air or a water condenser to prevent loss of volatiles and solvent. The sample container is located within a protective glass sheath. The organic solvent is then heated, by means of microwave energy, and refluxed through the sample.

A common commercial closed system (pressurized-MAE) is the MES-1000 microwave solvent extraction system (CEM Corp., USA). A schematic diagram of the pressurized-MAE system is shown in Figure 2. (Note: nine extraction vessels only are shown.) This system allows up to 12 extraction vessels to be irradiated simultaneously, in 1% increments, up to 950 W of microwave energy at 100% power. This system has in-built safety features, such as an audible alarm for the detection of an unexpected release of flammable and toxic organic solvent, a Teflon-lined microwave cavity, and an exhaust fan which continues to operate in the event of a solvent escape. Microwave conditions can be monitored via in situ pressure and temperature sensors (located within a single extraction vessel only). Pressure is measured using a water manometer that allows readings of up to 200 psi (1 psi = 6894.76 Pa) to be made. The temperature probe, a fiber optic with a phosphor sensor, allows extraction temperatures to be selected from 20–200 °C in 1 °C increments. Samples are placed into Teflon perfluoroalkoxy (PFA) vessels (100 mL capacity) which are themselves located within a polyetherimide protective casing (bodies and caps). Each extraction vessel contains a rupture membrane that is designed to fail at elevated pressure (200 psi). Each extraction vessel (up to 12) is located in a carousel which rotates through 180° during microwave operation. In the center of the carousel is an expansion chamber which is connected to each extraction vessel, and which acts to contain escaping vapors in the event of rupture membrane failure.

**Figure 2** Schematic diagram of a pressurized MAE system.

### 4 APPLICATIONS OF MICROWAVE-ENHANCED SOLVENT EXTRACTION IN ENVIRONMENTAL ANALYSIS

#### 4.1 Extraction from Solid Matrices

4.1.1 Atmospheric Microwave-enhanced Solvent Extraction

Akhtar and Croteau\(^5\) reported the extraction of sodium salinomycin (CAS 55721-31-8, referred to as salinomycin antibiotic) from finished chicken feed. It is added to the feed at a level of 60 mg kg\(^{-1}\). Salinomycin is used to prevent coccidiosis in broiler chickens. A conventional microwave oven (800 W) was used for the extraction followed by postcolumn derivatization high-performance liquid chromatography (HPLC). The feed (0.6 g) was placed in a polyethylene container and extracted with ethanol (15 mL) and propan-2-ol (2 mL) for 8 s. After irradiation, the organic layer was decanted off and the microwave process repeated twice more. All extracts (three times) were combined, centrifuged and evaporated to dryness. The residue was reconstituted in 10 mL of mobile phase. The results were compared with a conventional approach based on liquid–solid extraction and vortex mixing for 3 min. The same solvent system and volumes were used. The sample extract was treated the same as for the microwave extraction. The results in the finished feed were as follows: 34, 60, 103 and 160 mg kg\(^{-1}\) by MAE and 27, 45, 59 and 112 mg kg\(^{-1}\) using liquid–solid extraction. The expected values, based on calculation, were 30, 60, 90 and 150 mg kg\(^{-1}\). The authors concluded that MAE shows great potential for the monitoring of veterinary drug and pesticide residues in animal feeds and edible tissues and eggs.

Focused MAE (Maxidigest 350, Prolabo, France) was applied to the extraction of PAHs from reference materials (sediment, soil, air particulates) by Letellier et al.\(^6\) Initial studies were performed on marine sediment (National Institute of Science and Technology (NIST) standard reference material (SRM) 1941a) where it was found that small quantities of organic solvent (30 mL DCM) at short extraction times (10 min) and 30 W microwave power provided good recoveries (average recovery 87% for 13 PAHs) with standard deviations comparable to those obtained using Soxhlet extraction (2 × 250 mL DCM for 48 h). This approach was then applied to two other reference samples: soil (Community Bureau of Reference (BCR), certified reference material (CRM) 524) and air particulate/urban dust (NIST SRM 1649a). The results, compared to certificate values, were in good agreement (average recovery 97% with a relative standard deviation (RSD) of 6.4%, \(n = 18\)). The procedure was also applied to two sediment samples (industrial harbour marine sediment and yatching
Figure 3 Extraction of PAHs from contaminated soil. (Adapted from Saim et al.\textsuperscript{(7)})

detroit harbour sediment). The results, compared to Soxhlet extraction, produced slightly lower recoveries (average recovery 90\% with an RSD of 7.9\%, \( n = 24 \)). The benefits of this open MAE approach are the speed of analysis, simplicity of operation and safety in use. It is noted however, that the group did not include the most volatile PAHs in their remit, omitting two-ring aromatics, i.e. naphthalene (CAS 91-20-3).

Saim et al.\textsuperscript{(7)} compared the merits of Soxhlet extraction, pressurized-MAE, SFE and ASE with atmospheric-MAE for the extraction of PAHs from native contaminated soils. Atmospheric-MAE was done using a Soxwave-100 system. A 2-g soil sample was irradiated with 70 mL DCM for 20 min at 99\% power. The extract was filtered and reduced in volume to 5 mL prior to analysis. The results (Figure 3), for 14 PAHs, show that comparable recoveries are obtainable by all extraction methods. The sum of the 14 PAHs by each extraction technique were as follows: 1623, 1578, 1492, 1544 and 1537 mg kg\(^{-1}\) by Soxhlet extraction, pressurized-MAE, atmospheric-MAE, SFE and ASE, respectively. Finally, the individual PAH recoveries were statistically compared with Soxhlet extraction. It was found, at the 95\% confidence interval, that the majority of PAH determinations were not significant for MAE (atmospheric and pressurized). The authors concluded however, that the method choice, based on the data presented, still appears to be Soxhlet extraction.

4.1.2 Pressurized Microwave-enhanced Solvent Extraction

Pressurized-MAE is by far the most common approach that has been utilized for the extraction of organic pollutants from solid environmental matrices. Accordingly this section has been subdivided with respect to the analyte of interest.

4.1.2.1 Polycyclic Aromatic Hydrocarbons PAHs are the most commonly studied organic pollutant by MAE. As part of an on-going evaluation of new sample preparation techniques by the United States Environmental Protection Agency (USEPA), especially those that minimize waste solvents, MAE has been evaluated.\textsuperscript{(8)} Using a 1:1 hexane:acetone solvent mixture, the influence of extraction temperature (80, 115 and 145\°C) and extraction time (5, 10 and 20 min) on the recovery of PAHs from CRMs was compared with room-temperature extraction using the same solvent and contact time. It
was found that the average recoveries by MAE for the 17 PAHs studied ranged from 70–75%. The authors concluded that MAE offers reduced extraction time (typically 10 min for extraction and 40 min for cooling, centrifugation and extract concentration) and reduced solvent use (30 mL versus 300 mL for Soxhlet/Soxtec). In addition, up to 12 samples can be extracted simultaneously. This work was extended to incorporate a spiked soil sample with and without ageing. It was noted that recoveries from aged samples decreased, compared to freshly spiked samples. The same group extended this work to compare MAE with Soxhlet, sonication and SFE. Again freshly spiked soil samples were evaluated along with two CRMs. A whole range of compounds were considered (95 compounds in total). It was concluded that MAE gave superior or equivalent results to the other techniques considered. Of the compounds studied, the number of recoveries >80% was 51 by MAE, 50 by Soxhlet, 63 by sonication, and 37 by SFE. As an example, the recoveries of 14 PAHs from a certified sediment sample (SRM 1941a) by the different extraction techniques are shown in Figure 4.

Similarly, Dean et al. have evaluated the effectiveness of MAE for the extraction of PAHs from industrially contaminated soil. Initial work considered the robustness of MAE. It was found that acetone was the solvent of choice compared to hexane:acetone (1:1) and DCM only. An experimental design approach was used to investigate the dependence of operating variables (temperature, extraction time and solvent volume). These variables were considered between strict operating limits, i.e. temperature, 40–120°C; extraction time, 5–20 min and solvent volume, 30–50 mL. It was concluded that MAE was independent of the variables considered (and their limits) for the extraction of PAHs from native contaminated soil. The PAH recoveries from the soil by MAE (20 min extraction plus 30 min cooling time using 40 mL acetone) were compared with Soxhlet (extraction for 6 h using DCM), SFE (1 h extraction using 10% methanol-modified CO2) and ASE (12 min extraction using 25 mL acetone:DCM 1:1). It was found that MAE compared favorably with SFE and ASE. All techniques gave superior results compared to Soxhlet extraction. The sum of 16 individual PAHs was 422.9, 297.4, 458.0 and 421.0 mg kg\(^{-1}\) by MAE, Soxhlet, SFE and ASE, respectively. Solvent choice was considered to be an important variable for extraction of native contaminants.

Certified marine sediments and soil have been extracted by MAE and analyzed for PAHs. The sample (1–5 g) was irradiated with microwave radiation in the presence of 30 mL of hexane:acetone (1:1), for 10 min at 115°C. Recoveries of 14 PAHs from certified soil (standard reference soil (SRS)-103–100) ranged from 67% with an RSD of 22.1% for dibenzo[ah]anthracene (CAS 53-70-3) to 111% with an RSD of 10.2% for benzo[k]fluoranthene (CAS 207-08-09).

The certified values ranged from 14.2–1924.9 ppm. Similarly, recoveries of 16 PAHs from marine sediments

![Figure 4](image-url)
(HS-3, HS-4 and HS-5) ranged from 61% (naphthalene) to 275% (benzo[k]fluoranthene) for HS-3; 54% (naphthalene) to 156% (benzo[k]fluoranthene) for HS-4; and, 52% (benzo[a]pyrene, CAS 50-32-8) to 137% (benzo[k]fluoranthene) for HS-5. Average recoveries, based on 16 individual PAHs, for HS-3, HS-4 and HS-5 were 103, 88 and 79%, respectively. In addition, a further marine sediment was also analyzed (SRM 1941) for 15 PAHs. Recoveries ranged from 72.4% (perylene) to 130.2% (benzo[k]fluoranthene) with an average recovery, based on 15 individual PAHs, of 99%. The results for the extraction of PAHs from certified reference samples are summarized in Figure 5.

An evaluation of extraction solvent for the MAE of PAHs from sediment samples has been reported. Three solvent systems were evaluated: acetone:hexane (1:1), hexane:water and toluene:water. The acetone:hexane mixture was included in this study because it has been by far the most studied extraction solvent system for MAE. For the other two solvent systems, water was added at 10% (v/v) in all cases. MAE was done by placing the sample (2–10 g) and solvent mixture in a hermetically sealed polytetrafluoroethylene (PTFE) reactor and then irradiating at 660 W power for 6 min. After cooling, the sample container was opened and 8 g of sodium sulfate added to dry the organic phase. All extracts were then evaporated to dryness and dissolved in 2 mL hexane. Copper wire was then added to remove sulfur and the solution was finally passed through a microcolumn of activated Florisil and eluted with 30 mL of DCM:hexane (70:30 v/v). Finally, the extract was evaporated to dryness and dissolved in 200 μL solvent. Final extracts were quantified using gas chromatography (GC) with either flame ionization detection (FID) or mass selective detection (MSD). The recoveries, compared to Soxtec extraction, for a marine sediment were in agreement (average recoveries were 101, 99 and 102% using acetone : hexane, hexane : water and toluene : water, respectively). The automated Soxtec extraction was based on 2 g sample, 60 mL hexane : acetone (1:1 v/v) for 1 h sample immersion followed by 1 h of heating under reflux.

4.1.2.2 Hydrocarbons A method was developed for the quantitative extraction of gasoline- and diesel-range petroleum hydrocarbons from soil and marine sediment samples. Microwave operating parameters were evaluated using a two-level orthogonal array design. The operating parameters varied were as follows: solvent (DCM and acetone), temperature (80 and 115°C) and extraction time (5 and 15 min). It was found that the optimum conditions were: 30 mL of acetone at a temperature of 115°C and heated for 5–15 min. The effects of
wetting the sample on the recoveries of 14 hydrocarbons were investigated using spiked soil and marine sediment. Under dry conditions recoveries ranged from 60.0 to 88.3% with an RSD of 3.5–10.1% for marine sediment and from 60.4 to 89.6% with an RSD of 3.7–13.5% for soil. Under wet conditions (10% w/w) the recoveries improved; 80.5–100% with an RSD of 2.0–7.9% for marine sediment and 80.2–100.4% with an RSD of 2.3–7.4% for soil. The method was then applied to a range of local (Singapore) sediment and soil samples. It was concluded that the level of hydrocarbon contamination was low in the areas sampled.

MAE of linear hydrocarbons (C₁₆–C₃₂) from a lyophilized sediment sample using a mixture of toluene and water (90:10% v/v) is proposed. For further details of the experimental procedure, see section 4.1.2.1 on PAHs. The authors reported that, provided the microwave power was maintained above 66%, quantitative recoveries could be obtained irrespective of the extraction time (3–12 min). Similarly, maintaining a sample : toluene ratio greater than 1:2 provided quantitative recoveries. Extraction yields from the native sediment samples were assessed by comparison with Soxhlet extraction.

### 4.1.2.3 Polychlorinated Biphenyls

PCBs have been extracted from a range of CRMs (marine sediment and soils) using MAE. The following proven conditions were used: solvent, 30 mL of hexane:acetone (1:1 v/v); temperature 115°C; and extraction time 10 min. The recoveries compared with certificate values were as follows: Arochlor 1254 from marine sediment HS-1 and HS-2, 93.2 and 76.7%, respectively; Arochlor 1260 from Environmental Research Associates (ERA) soil (lot number 9801), 89.9%; and Arochlor 1248 from Superfund site soils, 102, 157, 86.8 and 75.3%. Values for the Superfund site soils were based on those obtained by an independent laboratory using Soxhlet extraction and gas chromatography/electrothermal capture detection (GC/ECD). The same certified reference samples (HS-1, HS-2 and the ERA soil) were analyzed by Lopez-Avila et al. to compare the method of detection (GC/ECD or ELISA (enzyme-linked immunosorbent assay) of the PCBs after MAE. It was found that the results closest to the certificate values were obtained using GC/ECD. However, it was concluded that the ELISA approach was more rapid. A batch of 10 samples could be prepared and analyzed in approximately 1 h.

### 4.1.2.4 Pesticides

Sample ageing, either artificially or by natural weathering, is an important factor to consider when evaluating any new extraction technique. However, it is unfortunate to note that most published methods for MAE are based on freshly spiked samples. Onuska and Terry aged a slurry spiked air-dried sediment for at least one month prior to MAE extraction of organochlorine pesticides (OCP). It was found that the optimum extraction conditions consisted of an extraction solvent of isooctane:acetonitrile (1:1 v/v), a minimum water content of the sample of 15% and an extraction time of >3 min. The results for the extraction of 15 OCPs from a spiked sediment sample (at spiking levels between 50 and 250 µg kg⁻¹) were good, the minimum recovery was 74% (3% RSD) for p,p'-DDE (1,1’-(2,2-dichloroethylenylidene)-bis(4-chlorobenzene) or 2,2-bis(4-chlorophenyl)-1,1-dichloroethylene) (CAS 72-55-9) while the best recovery was 95.3% (3.9% RSD) for methoxychlor (CAS 72-43-5).

The nature of the MAE process is such that heating can only occur if the solvent has a permanent dipole moment. As an alternative to the conventional approach, Hummert et al. utilized a microwave transformer (Weeflon®, an inert material based on carbon-containing teflon) to extract OCPs from seal blubber using a nonpolar solvent, e.g. hexane. It was experimentally determined that the best approach for MAE was to operate with seven extraction cycles (30 s duration at full power). Average recoveries for the seven organochlorine compounds from seal blubber were 96.9 ± 0.5%.

Extraction of a fungicide, hexaconazole, which had been weathered over periods of time up to one year was reported from two characterized soils. The soils, which had been collected at various times after application of the fungicide, were air dried for 48 h and sieved through a 2–3.5 mm sieve prior to storage at −18°C. The levels of hexaconazole in the two soil types were assessed using Soxhlet extraction, MAE, SFE and ASE. Extraction with microwave energy was done by irradiating a 5-g sample with 30 mL of acetone at 115°C for 15 min. The soil extract was then precleaned using C₁₈ SPE media and after elution with methanol the volume reduced to 1 mL. The results for the sandy clay soil (organic matter, 1.5%) were comparable by all extraction techniques (Figure 6). For example, the 52-week aged sample gave recoveries of 0.08, 0.072, 0.073 and 0.070 mg kg⁻¹ by Soxhlet, SFE, MAE and ASE, respectively. However, this was not

![Figure 6](image-url)
the case for the sandy loam soil (organic matter, 5.7%) where recoveries for the aged sample (52 weeks) were 0.07, 0.034, 0.035 and 0.093 by Soxhlet, SFE, MAE and ASE, respectively (Figure 7). It was concluded that ASE was unaffected by analyte–matrix interactions, providing good recoveries for all sample types.

4.1.2.5 Phenols The continued interest by USEPA in new sample preparation techniques has focused on a wide range of compounds including phenols. In this work, 16 phenolic compounds were extracted (30 mL acetone : hexane (1 : 1 v/v), at a temperature of 115 °C for 10 min) from freshly spiked clay soil, topsoil, sand, organic compost and topsoil with 5% humic acid. The recoveries of the phenolic compounds, spiked at the 95% confidence interval, were as follows: 1.5 μg g⁻¹ for o- and p-cresol, 4.4 μg g⁻¹ for m-cresol and 7 μg g⁻¹ for phenol; results obtained using a sonic probe were approximately half the values reported.

Figure 7 Extraction of hexaconazole from aged soils: sandy loam soil (organic matter, 5.7%). (Adapted from Frost et al.)

4.2 Extraction from Aqueous Matrices

4.2.1 Direct Extraction A novel approach for the microwave oven has been its use to extract chlorinated benzenes directly from water samples. An aqueous sample was placed in a screw-capped container located in the microwave oven. Through the cap of the container were inserted a helium purge line and an exhaust line. The exhaust line led to a trap which was cooled in an ice bath. This dynamic extraction procedure was completed as follows: aqueous sample (1 L) containing 20 g of salt was purged with helium for 20 min whilst operating the microwave oven at full power for 7 min. The extract was collected in the cooled trap. Excess water was removed by passing the extract through a microcolumn of anhydrous sodium sulfate; the column was eluted with 2 × 1 mL of hexane and concentrated under a stream of nitrogen to 2 mL. Further cleanup was necessary using a Florisil microcolumn prior to analysis. This approach was compared with the traditional approach of liquid–liquid extraction and found to compare favorably at the nanogram per liter level. Average recoveries for 10 chlorinated benzenes spiked into water at the 1 ng L⁻¹ level were 63% by a microwave-assisted process (MAP) and 69% by liquid–liquid extraction, while at the 10 ng L⁻¹ level the average recoveries increased to 93% by MAP and 98% by liquid–liquid extraction. The same group applied the approach to the extraction of PCBs from 500 mL of water. Recoveries of the spiked congeners, at two levels 85.5 and 209 by MAP were 90.9% compared with 80.6% by liquid–liquid extraction at a concentration of approximately 20 pg L⁻¹.
4.2.2 Solid-phase Extraction/Microwave Solvent Elution

MAE has been combined with SPE for the extraction of pollutants from aqueous samples. The procedure is as follows: analytes of interest are retained on a C\textsubscript{18} membrane disk (Empore), the disk is then rolled up and transferred into the closed PTFE-lined vessels of the MAE. Elution is achieved by placing organic solvent into the extraction vessel and irradiating the disk. The approach has been applied to a range of compounds, including OCPs, PCBs, PAHs, phthalate esters, organophosphorus pesticides (OPPs), fungicides, herbicides and insecticides, in aqueous solution. The operating variables have been optimized. The variables considered were: elution solvent (acetone and DCM); temperature (80, 100 and 120 °C); and extraction time (1, 3, 5 and 10 mins) at 50% power. The optimum conditions for microwave elution were acetone at a temperature of 100 °C for 7 min. Excellent results compared to liquid–liquid extraction, were obtained for PAHs and phthalates (spiked at 2 µg L\textsuperscript{-1}), OCPs (spiked at levels between 0.1–0.2 µg L\textsuperscript{-1}), PCBs (spiked at 0.5 µg L\textsuperscript{-1}) and OPPs, fungicides, insecticides and herbicides (spiked at levels between 1–2 µg L\textsuperscript{-1}) in either reagent water or seawater.

4.2.3 Gas-phase Microwave-assisted Extraction

The liberation of volatile organic compounds (VOCs) from water samples by microwave energy has been described by Pare et al. The aqueous sample is heated via a microwave oven, vaporizing VOCs into the headspace of the sample. By utilizing a conventional headspace sampler the VOCs are introduced directly into GC with FID. This approach was compared with a conventional 30 min static headspace sampling apparatus and the results obtained were favorable. It was noted, however, that the microwave approach gave higher detector responses, with better precision and in a shorter timescale than the conventional approach. The approach was subsequently extended to a range of volatile compounds including simple aromatics, i.e. benzene (CAS 71-43-2), toluene (CAS 108-88-3), ethylbenzene (CAS 100-41-4), \(\alpha\), \(m\) and \(p\)-xylene (CAS 1330-20-7), propylbenzene (CAS 103-65-1) and butylbenzene (CAS 104-51-8), as well as alkanes, i.e. C\textsubscript{8}, C\textsubscript{10}, C\textsubscript{12} and C\textsubscript{13}. In each case, a sensitivity enhancement was noted for the microwave approach (average enhancement factor was 4.4).

**5 CONCLUSIONS**

The use and application of MAE continues to expand. However, as the reader will be aware after reading this article, the diversity of operating conditions and solvent choice suggested by others, merely adds to the difficulty in accepting MAE in the laboratory. To assist the reader in this choice Table 2 contains guidelines for MAE method development. As pressurized-MAE is the most common approach, details for this mode of operation only are provided. The parameters shown in Table 2 are based on the use of a microwave system capable of delivering a minimum power of 900 W. Ideally, the microwave system should be equipped with the following safety features: a fan and appropriate ducting to allow ventilation of the cavity in the event of an organic vapor release; a solvent sensor that automatically shuts off the microwave source in the event of an organic solvent leakage (minimizing the risk of fire) and extraction vessels that will automatically vent into a solvent collection system at a preset pressure (to minimize the risk of explosion).

After a brief historical survey of the role of neutron activation analysis (NAA) in environmental analysis there follows a section on the main types of NAA and their application to environmental problems and a table of ideal sensitivities is given. The rest of the article deals with NAA as it is applied to the main divisions of the environment. Each of these sections includes a short summary of the sampling requirements suitable for NAA. Section 3 deals with its application to biological samples and includes a brief discussion on standard reference materials (SRMs) in NAA. Applications to various types of biological material are discussed, ending with a survey of biomonitoring using NAA. The next section (the longest) is the analysis of water by NAA. This is mainly based on the preconcentration and postirradiation procedures currently used for the major types of water (seawater, surface water and underground water). A table of element concentrations in seawater and surface water illustrates the low limits of detection required to determine many trace elements by instrumental neutron activation analysis (INAA). Applications are discussed in the main body of the text. There then follows a section on the use of NAA in air particulate analysis for trace elements. The importance of PM10s (particles with aerodynamic diameter less than 10 µm) to human health and the reasons for concentrating on the analysis of these particles by NAA is discussed. Having discussed the main areas of NAA used there follows an application section. Large-scale biomonitoring procedures are outlined, particularly those involving plant materials. The final section on major environmental divisions covers the use of NAA in analysis of soils and sediments together with the analysis of coal. This latter topic also includes on-line analysis of coal using isotope sources. Finally, there is a discussion of speciation and the function of NAA in environmental speciation, particularly atmospheric and aqueous speciation analysis.

1 INTRODUCTION

NAA is usually said to have begun with the work of Hevesy and Levi\(^ {1,2}\) on the analysis of the lanthanides, although it was only in their second paper that they described the determination of an element (Eu) by NAA. Having only weak neutron sources meant that the method remained essentially a curiosity. Virtually no further developments of the technique occurred until after the end of the Second World War and the availability of far higher neutron intensities from newly constructed nuclear reactors. These allowed analyses of samples at a sensitivity comparable to, or even better than, most other analytical techniques then available. This fact, combined with its inherent multielement capability, capacity to
analyze a large number of samples, ease of sample preparation and freedom from contamination following irradiation meant that it had many distinct advantages over comparable techniques such as atomic absorption spectroscopy (AAS), flame emission spectroscopy (FES), mass spectrometry (MS) and polarography. Despite some disadvantages, such as the availability of a large expensive reactor facility and its relative insensitivity for some elements of importance in toxicology and pollution it rapidly became the choice for multielement analysis.

Even by 1968, however, Meinke commented that NAA was not a panacea for all analytical problems and that it was best considered as only one of a number of analytical techniques which can complement each other. Thus, the best way of viewing the solution to an analytical problem is to regard the various techniques available as complementary and not competitive. No one technique (not even ICPMS (Inductively Coupled Plasma Mass Spectrometry)) is "best". Centers that provide a variety of analytical techniques are probably the ones that will provide the most accurate and wide-ranging analyses, particularly of environmental samples. On the other hand, the development of ICPMS systems with the provision for direct analysis of solids (using electrothermal evaporation, etc.) might see this technique assuming a dominant position.

Since the late 1970s a number of significant improvements have occurred, such as the routine use of epithermal neutron activation analysis (ENAA) and cyclic NAA, which have overcome some of the aforementioned problems for some important elements. NAA, however, is now regarded as a "mature" technique, i.e. one which has reached a plateau as far as new developments in the techniques expected in the future.

Several books and reviews on NAA have been published detailing the technique and its applications but few deal exclusively, or even substantially, with environmental applications. Probably the best of these is the two-volume book edited by Alfassi which covers the techniques and methodology in volume I and environmental applications in volume II. An older but still very useful book which deals more with radioanalytical NAA in environmental analysis is that by Das et al. as well as a similar book by Tolgyessy and Kyrs. There is a review article by Eisenbud of the whole field and one by Ehmann and Vance. This covers advances in NAA to 1989, including environmental analysis. Other good review articles have appeared on the role of NAA in air particulate analysis. Other areas of environmental research have not been so well reviewed. Starting in 1986, Ehmann et al. periodically published literature surveys covering all fields of NAA, including applications in environmental analysis, until 1994. Yates published a similar survey in 1997.

## 2 SCOPE OF NEUTRON ACTIVATION ANALYSIS

The actual technique and instrumentation used in NAA has been discussed in articles Chemical Analysis by Nuclear Methods: Introduction, Instrumental Neutron Activation Analysis and Nuclear Detection Methods and Instrumentation. NAA is usually subdivided into (1) INAA, which is nondestructive and is purely instrumental and (2) radiochemical neutron activation analysis (RNAA), which involves dissolution of the sample and some more or less complex chemical separations, usually postirradiation. RNAA produces the ultimate in sensitivity limits for the method and is essential for determining certain elements such as P and Tl in any matrix, or particular elements in specific matrices, owing to inherent interference in the γ-ray spectrum. The penalty to be paid for this improvement in sensitivity and precision is that of complexity and time for analysis. INAA is a much simpler technique and geared to processing quite large numbers of samples in a relatively automated way while still retaining good accuracy and precision. It is, therefore, the method usually chosen, if possible. Probably, still the most widely used method of NAA is the comparator method, using several single element standards or a single, multielement standard. The development of single element comparator methods (especially the $k_0$ method), has reduced analysis time and improved accuracy.

INAA can be further subdivided into thermal (and epithermal) NAA and fast neutron activation analysis (FNAA). Thermal NAA takes advantage of the high intensity of neutrons available from the thermalization of fission neutrons in a nuclear reactor and the large thermal neutron cross-sections for most isotopes. This makes the technique suitable for trace element determinations which is its major application in chemical analysis. INAA usually refers to its use with reactor thermal neutrons. Sensitivities for element determinations by INAA are matrix dependent but some calculated values for interference-free sensitivities are given in Table 1.

An additional factor in environmental research is the fact that the matrix elements C, H, N and O produce no significant activity and so virtually no interference problems. Other matrix elements such as Mg, Al, Si and Ca give rise to fairly short-lived activities that may only interfere with a few short-lived trace element radioisotopes.

FNAA usually refers to irradiations with neutrons with the specific energy of 14.7 MeV. FNAA is not usually regarded as a trace element technique owing to the much lower fluxes generally available and the generally much smaller reaction cross-sections. The major exception to this rule is for the determination of oxygen.

$^b$ Sensitivities based on the following parameters: $\phi_{th}$ = 10$^{17}$ nm$^{-2}$ s$^{-1}$, irradiation time = 5 h max., decay time = 0, count time = 100 min max., 40 cm$^2$ Ge (Li) detector with nuclide 2 cm distance.

$^c$ Elements are listed in a given group in decreasing order of sensitivity.

where FNAA is probably the most sensitive technique available.

ENAA is a useful extension of INAA in that it enhances the activation of a number of trace elements relative to the major matrix elements. Here, epithermal is taken to be neutrons with energies from the Cd cut-off of 0.55 eV up to approximately 1 MeV. In general, the activation cross-sections of the matrix elements of environmental samples are inversely proportional to the neutron energy (1/v law). The trace elements also follow this general trend but many of them have large activation cross-sections at specific energies in the epithermal energy region. Thus, in irradiations with mainly epithermal neutrons the relevant trace elements are well activated and the resultant $\gamma$-ray peaks are usually more distinct and so more precisely analyzed than when using thermal NAA, even though the peaks may actually contain less counts. ENAA is particularly useful for biological and seawater samples which contain high concentrations of Na and Cl, which follow the 1/v law.

Finally, a number of more specialized techniques can be used to enhance the sensitivity of INAA. One of these is cyclic instrumental neutron activation analysis (CINAA), which is used to improve the measurement of some very short-lived isotopes (e.g. Pb, which can be activated to $^{207m}$Pb with 0.8 s half life) by repeated irradiation and counting. CINAA has also been used to improve the determination of Cu, F, Pb and Se amongst others, in biological samples.

A special form of INAA results from the $\gamma$-rays emitted immediately following the capture reaction. These are known as prompt gamma rays and, hence, the method is called prompt gamma neutron activation analysis (PGNAA). Here, irradiation and counting have to be undertaken simultaneously but in principle, all elements are determinable by PGNAA since all elements capture neutrons but detection limits (DLs) vary from $\sim$0.1 ppm up to tens of ppm depending on the element and the available neutron flux. Chau et al. have discussed the wider application of PGNAA to environmental and biological materials.

3 ANALYSIS OF BIOLOGICAL MATERIALS

3.1 Introduction

The determination of the minor and trace elements in biological materials can have a number of objectives. One
of these is to estimate the normal or baseline concentrations of elements so that any significant deviations from these levels can perhaps be related to specific changes or diseases in the organism or tissue. A second objective is to determine those elements deemed essential or toxic to an organism and at what levels they function in these roles. Thus, in humans some 18 elements (Ca, Cl, Co, Cr, Cu, F, Fe, I, K, Mg, Mn, Mo, Na, Ni, P, S, Se and Zn) are now thought to be essential for the correct metabolism of an individual, ranging from a daily requirement of 2–5 g for K down to 3 µg for Co. It is well known, however, that almost any substance taken in excess will ultimately become harmful, i.e. toxic. In other words, there is no essential qualitative difference between essential and toxic elements. A third objective of trace element determinations is to ascertain if the concentration of an element(s) in a particular tissue or component can be an indicator of a specific disease. An example is the elevated concentration of Cu in the livers of people suffering from Wilson’s disease.

3.2 Sampling

In environmental monitoring the quality of the data is related to three principal factors: (1) the design and performance of a representative sampling program, (2) the satisfactory storage of the sample to prevent changes to the analyte and (3) the use of suitable analytical methods which yield the requisite accuracy and precision.

Sampling is a problem for all types of material but sampling of biological materials is particularly difficult. This is in part due to the very complexity of the components of biological samples but also in part to the often limited amounts available and to potential changes to the constituents following sampling, e.g. coagulation of milk and blood or general bacterial attack. Thus, sampling may be the key factor in the quality of the data for some biological analyses.

3.2.1 Methods of Sampling and Sample Preparation

An important consideration in the collection of vegetation for any type of analysis is that the sample variation within a collection area probably greatly exceeds all other analytical variations. This necessitates careful consideration being given to the collection strategy and will often require proper statistical design for sample collection if meaningful results are to be obtained. Such considerations are beyond the scope of this article but are treated by, for example, Barnett(17) and Webster.180 Vegetation in this context could include grasses, vegetables of all sorts, leaves of trees or needles from conifers and fresh water and marine plants, particularly seaweed.

Sampling tissues, organs, and so on is a specialized job and normally the analyst will be supplied with the necessary material from a suitable laboratory. Urine and faecal samples may be required from both humans and animals, and suitable arrangements for their collection are required.

3.3 Standard Reference Materials

In order to verify the quality of the data from INAA, the availability of SRMs with certifiable (trace) element concentrations is important. They may also be used as standards in some circumstances in the comparator method. Some 200 SRMs are now currently available, covering virtually all the matrices met within the analysis of biological materials. The International Atomic Energy Agency (IAEA) in Vienna has issued a comprehensive list of these SRMs and their suppliers.19 Such materials conform to the basic requirements of certifiable element concentrations, homogeneity and long-term stability. Byrne20 has given a useful survey of the role of SRMs in environmental monitoring.

3.4 Irradiations

Biological samples are normally irradiated in acid-cleaned polythene vials for irradiations up to a day or so. For much longer irradiations, quartz ampoules are normally used. These must be cleaned in boiling aqua regia followed by thorough rinsing in doubly distilled water prior to irradiation. A blank irradiation, with no sample present is usually necessary owing to the presence of trace impurities such as K, Na, Sb and Sc in the silica. A suitable standard(s) is used in the comparator method, although Byrne and Dermelj21 have described a method based on the use of an endogenous internal standard of already known concentration for the analysis of biological samples which eliminates the need to know the sample mass and greatly reduces errors due to geometrical differences, and in RNAA it eliminates the necessity of determining chemical yields.

Owing to the generally low concentrations of nonmatrix elements in biological samples coupled with the fact that the matrix elements (C, H, N, O and P) do not produce γ-emitting nuclides, biological samples are often irradiated for long periods to enhance the activities of the analytes. The problem of bremsstrahlung from some of the induced β-emitters (e.g. 32P) is reduced by placing a plastic absorber between the samples and the detector. Using a flux of approximately $10^{17}$ nm$^{-2}$ s$^{-1}$ the sensitivity for many elements is inferior to that of many other analytical procedures and is frequently slower. Even if fluxes greater than $10^{17}$ nm$^{-2}$ s$^{-1}$ were available, they could rarely be used for biological samples owing to the radiation damage that they would cause.
In INAA of biological materials, the normal procedure is to use a short irradiation of about 30 min to determine short-lived nuclides such as $^{27}$Al, $^{27}$Mg, $^{47}$Ca, $^{52}$V, $^{56}$Mn, $^{86}$Br, $^{86m}$Rb, $^{101}$Mo and $^{128}$I, together with $^{24}$Na, $^{42}$K and $^{82}$Br. Very short-lived isotopes such as $^{30m}$Cl (710 ms), $^{79m}$Br (4.8 s), $^{20}$F (11.1 s) and $^{77m}$Se (18 s) can also be determined using a pneumatic transfer system in the technique of short-time NAA. Here, CINA may be effectively used to increase the sensitivity of the determination. Short-time NAA allows the determination of some elements, e.g. Pb and Se, that would otherwise require a postirradiation chemical separation. These short irradiations are then followed by a long irradiation of 8–48 h duration for the determination of $^{51}$Cr, $^{59}$Fe, $^{60}$Co, $^{65}$Zn, $^{76}$As, $^{86}$Rb, $^{121}$Sb, $^{137}$Cs, $^{138}$Ba, lanthanides, $^{182}$Ta, $^{233}$Th and $^{233}$Pa(U). INAA is very useful for samples that are difficult to obtain, such as biopsy samples. Because of the essentially nondestructive nature of the technique, the samples are available for repeated determinations or analyses by other methods.

The high activities of $^{24}$Na, $^{38}$Cl, $^{56}$Mn and $^{82}$Br induced in most biological samples mean that many trace elements can only be determined after pre- or postirradiation chemical separation to remove these interfering nuclides or alternatively, by employing ENAA since the interfering nuclides follow the 1/$v$ law. ENAA is particularly useful for the determination of Ag, As, Br, Cd, Cs, I, Mo, Rh, Sb, Se, Sr and Zn. Silicon can be determined by ENAA in biological materials but the corrections for the interfering $^{31}$P($n$,α)$^{28}$Al and $^{27}$Al(n,γ)$^{28}$Al reactions are so large for fruit, legumes, meat and milk as to make the method inapplicable. Both Cd and B compounds have been used as thermal neutron absorbers, although there can be thermal problems when using boron compounds (BN and B$_4$C$_3$). ENAA is also used as a complement to INAA and ENAA to extend the range of elements determined in biological materials, e.g. N, P, Si and Ca. It has been used particularly for the determination of nitrogen which, in turn, has been used as an estimate of the protein content of samples. The reaction used is $^{14}$N(n,2n)$^{13}$N, giving a positron-emitting nuclide with a half-life of 9.97 min.

Some elements in biological samples are also determined by PGNAA. It is particularly useful for boron determinations using the 478-keV γ-ray from $^{10}$B. The nondestructive nature of the method makes it useful for studying the uptake of boron by plants from the soil.\(^\text{22}\)

### 3.5 Radiochemical Separations

Although for reasons discussed in section 1, instrumental forms of NAA are usually preferred because of the simplicity and ability to process large numbers of samples in a relatively short time and to retain the sample intact, nevertheless, for certain applications there is no escaping dissolution of the sample and chemical processing. Generally, postirradiation separations are favored because of the lack of contamination problems but occasionally preirradiation separations must be used. In either case, the procedures for the dissolution of materials may result in the loss of more volatile trace elements such as Hg, I, Sb, Se, and when dry ashing is used, even elements such as Ce, Co, Mn, Pa, Ru and Zn can be partly volatilized, even at low ashing temperatures.

#### 3.5.1 Preirradiation Separations

These are usually performed when there is the possibility of rapid sample deterioration or in order to reduce the amount of activity to be handled after the irradiation. In either case, either the analyte is separated or the matrix elements removed. When using preirradiation separations, because there is the possibility of chemical contamination, a blank determination is necessary. The removal of sodium prior to irradiation may be required owing to its short half-life (15 h) and the intense activity that may be induced in some samples. This can be achieved by dissolving the sample, stirring in powdered hydrated antimony pentoxide (HAP) and then filtering to remove the HAP which will contain most of the sodium.

#### 3.5.2 Postirradiation Separations

In order to improve the sensitivity of the determination of a number of elements by removal of spectral interferences, or to enable a general reduction in the background activity and elimination of any blank value, a postirradiation separation is used. An important aspect of modern RNAA is the development of standardized and automated separation systems which can handle relatively large numbers of samples and are less prone to radiation hazards, although these tend to be laboratory specific. It has been found to be more effective to have a number of separate separation procedures for a number of small sets of elements rather than a single complicated procedure for all the elements, usually at the expense of high and constant yield.\(^\text{23}\)

The majority of postirradiation separations use either ion-exchange chromatography or solvent extraction but precipitation is also used. Here the addition of carriers is essential for all the analyte elements as well as major interfering elements. Platinum has been determined by electrodeposition from acid solution using a cell with a niobium cathode. A DL of about 1 ppb has been achieved with this technique.

A more recent development has been the introduction of new ion-exchange materials, particularly inorganic exchangers. An interesting example is analysis for Li which can be determined in biological materials by
using the following reactions: $^6\text{Li}(n,\alpha)\text{T}$, $^{16}\text{O}(t,n)^{18}\text{F}$. The sample solution is placed on a ZrO$_2$ column and the $^{18}\text{F}$ absorbed. Interfering nuclides are eluted off with pH 1 to 3 solution and the column then counted to determine the $^{18}\text{F}$ activity. (24) These developments have been reviewed by Braun et al. (25)

One of the more rapid methods for the separation of trace elements following dissolution of the sample is by adsorption on activated carbon (AC). (26) The solution is simply filtered through a layer of AC on a membrane filter. The number and type of elements that are collected in a single filtration can be varied by the addition of certain reagents to the solution. Thus, filtration at low pH without the addition of any reagents will result in the adsorption of $^{64}\text{Cu}$, $^{110m}\text{Ag}$, $^{197}\text{Hg}$, $^{198}\text{Au}$ and $^{233}\text{Pa(Th)}$. If the filtrate from this is then treated with ammonium pyrrolidine dithiocarbamate (APDC) and oxine and filtered again through fresh carbon, this results in the adsorption of $^{64}\text{Cu}$, $^{99m}\text{Mo}$, $^{122}\text{Sb}$, $^{187}\text{W}$ and $^{197}\text{Hg}$. This can be extended to the point where some 15–25 radionuclides can be collected on different carbon fractions which can then be counted to determine the relevant nuclides.

3.6 Applications

3.6.1 Tissues, Blood and Bone

Almost all human organs and tissues have been subjected to analysis by INAA. Many of these studies have simply determined the levels of all the detectable elements. Others have been used to assess levels connected with specific diseases. Some international comparison studies have revealed the difficulties in obtaining reliable data for some elements in some tissues. Values for As, Cd, Hg and Pb obtained by a number of analytical techniques including NAA in bone, lung and brain samples are rather poor.

A number of studies have focused on the analysis of the brain by INAA with attempts in particular to try to relate instances of decreased concentrations of specific elements with Alzheimer's disease. (27) It is well known that high concentrations of Al in the brain are associated with the disease but other trace elements may play a role.

Blood has been widely analyzed by INAA, again with much of the emphasis on the concentration range of trace elements found in blood or blood components. (28) Some efforts have been made to correlate various diseases with blood composition and there is evidence for some specific changes of blood composition for some occupational groups. Also, certain elements (e.g. La and Tb) tend to increase in concentration with age.

Much of the work on bone has been directed primarily at determining the fluoride content of the bone, due to the potential role of fluoride in the development of bone diseases. This has also led to investigations of changes of other elements in bone such as Al, Ca, Mg, Na and P from various diseases or forms of treatment. Al, Mg and Na are all best determined by INAA but F-NAA is the more sensitive method for Ca, F and P. If lower energy neutrons (<10 MeV) are used, the most sensitive $^{19}\text{F(n,}\alpha)^{16}\text{N}$ reaction is effectively employed. (29) An interesting application of bone analysis is the correlation of the N/F ratio in fossil bones with the age of the bone, F increasing with age as it replaces the P in apatite. (30)

3.6.2 Biomonitoring

An increasing trend in environmental analysis is that of biomonitoring. Here, some living system (usually a plant) which incorporates and concentrates a particular pollutant is sampled and used to estimate the total amount of the pollutant over a wide area or to estimate the effect of pollutants on the local ecosystem. In this way the biomonitor records environmental changes and can be used to follow the effect of changed pollutant conditions. Alternatively, from determining the concentration of a particular pollutant in specific tissues or body fluids in human beings, biomonitoring can be used to estimate better the total dose absorbed and to assess the risk of environmental or occupational exposure to the pollutant.

Since the late 1960s there have been numerous studies of the trace element composition of human hair (and to a lesser extent, nails) with the aim of estimating patterns of composition for normal populations in a given region or geographical area and then using these “normal” patterns to reveal significant variations which may indicate exposure to high levels of a pollutant or possible correlations with certain diseases. The IAEA has coordinated international programs of nuclear-based research on hair analysis. (31,32) The later IAEA program (32) was directed towards collection of hair only from males of a certain age who died by accident or were subject to sudden unexpected death.

The data from the first IAEA program provided data on 40 elements. It showed that use of geometric means and standard geometric deviations gave a much better characterization of the distribution of trace elements in most cases than the equivalent arithmetic ones. Also, statistical variations of element concentrations could be quite large without being “abnormal”. Studies have also revealed geographical differences in some elements, e.g. Se higher in Asian than European populations.

More frequently, however, the interest is in how the concentration of elements in hair reflects internal contamination or burden of an element(s). An example is that of peasants who consumed grain contaminated with a mercury fungicide. (31) Many of these ingested toxic
quantities and variations along the length of hair recorded the history of the poisoning.

3.6.3 Plants

The analysis of trace elements in plants has proved a fruitful field for both RNAA and INAA. Again, much of the work has concentrated on determining the range of trace elements found both in whole plants and in different plant structures such as seeds. Essentially the same 15–20 elements found in biological materials are also determined in plants by INAA.\(^{(33)}\) RNAA then yields a further 10–12 elements, among them Ag, Au, Cd, Cu, Hg, Mo, Sr and Zn. FNA and ENAA also extend the range of elements determined, including nitrogen which is useful for determining the protein content of plants.

4 ANALYSIS OF WATER

4.1 Introduction

The analysis of water for trace elements and, in particular, trace metals is one of the most important aspects of environmental monitoring. This results from the role of water in all aspects of life on our planet, ranging from the purity of drinking water to the pollution levels in the seas and oceans. At the same time the seas provide a valuable source of some heavy precious metals. In addition, the data obtained can be used to elucidate transport processes in the aquatic environment.

Water can be broadly segregated into sea, surface (lakes, rivers, drinking, etc.), ground and waste. Apart from the latter, levels of most elements in water are at the trace or ultratrace level (see Table 2). The exceptions to this general rule are the concentrations of Na, Cl and Br and one or two other elements, particularly in seawater. Levels of certain elements in wastewater can also be high but vary according to the source of this water.

In one respect, water presents the perfect matrix for determinations of trace elements by NAA since it is essentially not activated. On the other hand, the low concentrations of most elements would require the use of large sample volumes and long irradiations with high neutron fluxes for measurements by INAA. These requirements present several problems: first, there is a

\(^a\) Data from Seawater: Its Composition, Properties and Behaviour, Open University Course Team, Pergamon Press, Oxford, 1989.\(^{(34)}\)

severe limitation on sample size in most reactors and second, long or intense neutron irradiation of water results in the radiolysis of the water leading to problems from the subsequent gas generation. Shorter irradiation times result in unacceptably long counting times. A final factor militating against INAA of many water samples is the high activities of $^{24}\text{Na}$, $^{38}\text{Cl}$ and $^{82}\text{Br}$ induced in these elements. Although these are all relatively short-lived activities, it makes handling the sample following irradiation difficult and precludes the determination of the short-lived trace elements in many cases.

Consequently, water as such is rarely irradiated (although methods have been developed to allow irradiation of large volumes of water, up to 250 cm$^3$ for 20 h) and the more usual approach is to concentrate the elements prior to irradiation in a solid form (pre-concentration) or, more rarely, following the irradiation (post-concentration).

4.2 Sampling

Environmental sampling of liquids will usually involve liquids flowing in open systems (rivers, canals, effluent streams, etc.) or liquids in large open bodies (seas, lakes, ponds, etc.). The major difficulty in sampling flowing liquids for this type of system is that it may vary in two dimensions, i.e. both with depth and along its length. The sampling will probably have to take into account changes in flow rate, both seasonal and on a shorter timescale.

Samples are collected in wide-mouth bottles or small buckets, probably of plastic construction. If samples are required at various depths then special containers are used which can be filled at a specific depth and then closed before removal to the surface.

For water in large open bodies it will again probably be necessary to obtain samples from various parts of the body and at various depths. The samples can be taken with similar devices discussed above. Special devices have also been constructed for sampling relatively shallow lakes and ponds on a regular basis to obtain samples quickly from several fixed depths.

4.3 Preconcentration Procedures

4.3.1 Evaporation and Freeze Drying

These are both simple methods, can handle large volumes of water and are free of potential chemical contamination. They do, however, suffer from the time required for their completion and the fact that no reduction in the Br, Cl or Na content occurs. Freeze drying is preferred as even evaporation at relatively low temperatures can result in the loss of some volatile elements and possible contamination of the open system. The resultant solid that is produced can then be subject to INAA with the above limitations due to the presence of Br, Cl and Na.

4.3.2 Chemical Preconcentration

The aim here is to concentrate the trace analytes whilst separating them from potential interfering elements at the same time. In general, the most useful methods are those that concentrate a large number of trace elements, although procedures have been developed for the concentration of a small number of elements that are of particular concern or troublesome to determine by alternative concentration techniques. The most appropriate method will be one which is rapid and can actually be carried out at the sampling site, thus eliminating problems due to adsorption or desorption during storage of the sample. Examples of such methods are filtration, adsorption of the analyte during passage of the water through a column of a suitable solid, solvent extraction or the collection of a precipitate. Direct precipitation is usually not possible owing to the very low levels of most of the elements. The answer is to use coprecipitation whereby a suitable bulk chemical is precipitated and this carries the trace elements. In particular, organic coprecipitants are suitable as C, H, O and N do not form radioisotopes except for small amounts of very short-lived $^{16}\text{N}$ and $^{18}\text{O}$. Alternatively, the trace elements may be scavenged from solution by a suitable solid, e.g. MgO and AC. A method requiring more time and involving greater complexity is ion exchange, mainly of complexed species. Rarely, electrodeposition is used for some specific elements (e.g. Hg). The enrichment factors for these techniques, however, are usually much smaller than those obtained by coprecipitation methods.

The major drawback of preconcentration is the potential contamination of the final product by the chemicals used. Hence, the emphasis is on the purity of all the chemicals used in a procedure. A second disadvantage is the necessity to determine a blank value for the elements determined, in other words, carry out the entire procedure with very pure water to determine the contamination from the procedure itself. Finally, the chemical yield for the analytes must be determined or it must be established that a given procedure produces an essentially quantitative yield. Despite these drawbacks preconcentration methods are the most widely used in the analysis of water samples by NAA.

4.3.2.1 Coprecipitation

Coprecipitation may be conveniently divided into methods based on either organic or inorganic precipitants. Some more recent organic precipitants have also incorporated metals that produce only very short-lived or long-lived $\gamma$-emitting nuclides or only $\beta$-emitters to increase yields, e.g. Pb and Bi in conjunction with the precipitant pyrrolidine dithiocarbamate (PDC).

ENVIRONMENT: WATER AND WASTE
**Organic Precipitates.** A number of organic compounds, mainly chelates, have been used in preconcentration by coprecipitation. Thus, oxine (8-hydroxyquinoline) is used for the determination of Cd, Cu and Mn in seawater, and in the form of reversed-phase extraction, chromatography using silica-immobilized oxine has been developed for the simultaneous determination of Co, Cd, Cu, Hg, V and Zn in rain and surface waters.\(^{(36)}\)

Dithiocarbamates, in the form of the Pb or Bi salts of PDC carry many elements when coprecipitated with them, which is carried out at pH < 6 for the best yields for most elements. APDC in the presence of Bi\(^{3+}\) carrier carries Cd, Co, Cu, Mo, V and Zn quantitatively from lake and river-water samples\(^{(37)}\) and arsenic as As(III) has been determined in surface waters by precipitation of the dibenzylthiocarbamate complex followed by filtration and then INAA of the solid. Dithiocarbamic acids possess an S–H group which is readily oxidized in aqueous solution to insoluble disulfides which form the precipitate. Some other organic molecules with oxidizable S–H groups have been examined as potential coprecipitants,\(^{(38)}\) in particular quinolyl-8-thiol and its derivatives which give rise to bis(8-quinolyl) disulfides. Waters with high fulvic or humic acid concentrations result in poor or no coprecipitation of trace metals and so these organic contaminants in the water have to be destroyed prior to disulfide coprecipitation.

PAN (1-(2-Pyridylazo-2-naphthol)) when added as a dilute solution in ethanol to the water sample results in the PAN crystallizing out, whereupon the solid is filtered and collected for irradiation. In this way, excellent recoveries of Cr(III), Cu, the lanthanides, Mn(II), Ni and Zn can be obtained together with lower recoveries of Ag, Cd, Cu, Hg, V and Zn in tap water and seawater.\(^{(39)}\) Under these conditions, preconcentration factors > 2 × 10\(^2\) are possible. Combinations of these precipitants with each other or other organic complexes are also used to improve the yield or separation of various elements. Examples are bismuth salts of mixed oxine and thionalide (2-mercapto-N-2-naphthylacetamide) used in combination with Pb or Bi salts of (PDC) for the determination of As, Cd, Co, Cr, Cu, Fe, Hg, In, Sc, Sn, Th and U in surface and seawater.\(^{(40)}\) Under these conditions, preconcentration factors > 2 × 10\(^2\) are possible. Combinations of these precipitants with each other or other organic complexes are also used to improve the yield or separation of various elements. Examples are bismuth salts of mixed oxine and thionalide (2-mercapto-N-2-naphthylacetamide) used in combination with Pb or Bi salts of (PDC) for the determination of As, Cd, Co, Cr, Cu, Fe, Hg, In, Sc, Sn, Th and U in surface and seawater. A mixture consisting of APDC, Cupferron and 1-(2-thiazolylazo)-2-naphthol (TAN) can be precipitated from drinking water and seawater samples at pH 6 for the determination of Cd, Co, Cu, Hg, Mn, Th, U, V and Zn.\(^{(40)}\) Finally, oxine is also used to determine Al, Cu, Mo, V, U and Zn in underground, lake and seawater by converting these metals to oxine chelates, extracting these with molten o-phenylenediamine and irradiating the subsequently cooled solid.

**Inorganic Precipitates.** A problem with some potential precipitates is that the matrix metal, e.g., Fe, is activated requiring its removal either prior to irradiation or prior to counting. Fe(OH)\(_3\) has been used to collect a number of trace inorganics from water. Arsenic in seawater can be determined by coprecipitation with Fe(OH)\(_3\), with the precipitate redissolved in acid and the solution irradiated.\(^{(41)}\) The As (\(^{75}\)As) is isolated on a column of Al\(_2\)O\(_3\) for counting. The same precipitant can be used for the determination of several lanthanides in river and seawater following a group separation after irradiation. A combination of Fe(OH)\(_3\), Al(OH)\(_3\) and PbS has been used to determine a number of elements in river water, each coprecipitant removing a specific set of elements.\(^{(42)}\) PbS coprecipitates Ag, Al, Ba, Br, Cl, Cu, I, In, K, La, Mg, Mn, Na, Sb, Sn, Sr, U, V and Zn from various potable mineral waters. Lead phosphate has also been used to coprecipitate Ag, Cd, Cr(III), Cu, Mn(II), Th(IV), U(VI) and Zr(IV) from surface and seawater.\(^{(43)}\) Bismuth sulfide, Bi\(_2\)S\(_3\), has been used to coprecipitate a limited number of elements, e.g., Pd in seawater. Short irradiations produce no activity from Pb or Bi and the beta activity from the sulfur and phosphorus is not a problem.

### 4.3.2.2 Scavenging

This term as used here refers to the process whereby a finely divided solid such as carbon or MgO is added to the water sample with the aim of adsorbing trace elements present. The process may, in fact, involve physicochemical processes other than adsorption, such as ion exchange. In general, scavenging satisfies the requirements of a fast simple means of preconcentration.

By far the most widely used method of scavenging is that based on AC.\(^{(26)}\) In its simplest form, this simply requires the water sample to be stirred with a suitable mass of AC (or for the water to be poured through a column of AC), followed by filtration to collect the AC and then irradiation of the dried solid. Ultrapure carbon results in virtually no activity since the carbon itself is not activated and only trace impurities produce \(\gamma\)-emitters. The levels of these trace impurities vary according to the source of the carbon and this requires a blank measurement, so that the sample data can be corrected where necessary. Preparation and irradiation of a blank are necessary for all scavenging techniques.

In practice, it is found that adsorption isotherms for almost all elements are increased by chelation of the element so that the element is adsorbed as the chelated species.\(^{(26)}\) Commonly used chelates are APDC (Cd, Co, Cr, Cu, Mn, Mo, V and W) and L-ascorbic acid (Se, U). Bismuthyl-II (3-phenyl-5-mercapto-1,3,4-thiadiazole-2(3H)-thion potassium salt) has also been used to chelate Se. For Hg no chelation is used but the
Magnesium oxide, MgO, was originally applied to the determination of trace elements in surface water.\textsuperscript{44} In this process light MgO is stirred with the water for 30 min and then allowed to stand for \(~8\) h. This produces a stable mixture of MgO and Mg(OH)\textsubscript{2} of pH 10, which then adsorbs trace elements from the water via an ion-exchange mechanism. The filtered and dried solid can be subject to INAA since, again, Mg does not produce any long-lived activity. In this way, Ag, As, Au, Cd, Ce, Co, Cr, Fe, La, Mo, Ni, Sb, Sn, U and Zn are all absorbed. Washing the irradiated MgO with water removes interfering $^{24}\text{Na}$, $^{42}\text{K}$ and $^{82}\text{Br}$. It is also found that the lower oxidation states of some elements are much better absorbed than the higher ones \([\text{Cr(III)} \succ \text{Cr(VI)}, \text{Sb(III)} \succ \text{Sb(V)}, \text{Se(IV)} \succ \text{Se(VI)}]\). This provides for the possibility of separating the oxidation states of these three elements. When MgO scavenging is used for seawater, adsorption from acidified seawater is necessary in order to destroy the chloro complexes of some metals such as Hg and Ni and allow their absorption as the cationic species.

\subsection*{4.3.2.3 Ion Exchange}

The method is used not only as a preconcentration technique, but also as a means of removing many interfering elements from natural waters. A great advantage of ion exchange over other preconcentration techniques is that virtually unlimited volumes of (nonsaline) water can be used in the exchange of trace elements. After washing the column, the resin can be removed, dried and subjected to INAA. For conventional acidic cationic or basic anionic exchangers, seawater is obviously a particular problem owing to the presence of large amounts of Br, Cl and Na in particular and they are not normally used. In general, anionic exchangers are more widely used than cationic ones for the preconcentration of trace metals from surface waters, and metals determined in this way are Ag, As, Au, Cd, Co, Cu, Hg, Mn, Th, V and Zn.

In the case of seawater, the choice is usually between a chelating resin or an inorganic exchanger. Chelating resins readily take up those metals that form strong chelates with the functional group. This excludes Na to a great extent so that large volumes of seawater can be used. Such resins take up Al, Ca, Cr, Eu, Fe, La, Mn, Mo, Ni, Sc, Sn, Ti and V in addition to those mentioned with anion exchangers. Thus, carboxymethylated polyethyleneiminepolymethyleneephenylene isocyanate chelating resin can be used for the preconcentration of Cd, Pb and Zn from seawater or Cd, Co, Cu, Hg and Zn from surface water by shaking the water with the resin beads. Enrichment factors of \(~400\) are obtained with this material.\textsuperscript{45}

Conventional polystyrene powder containing conformationally flexible aminocarboxylic acid groups have high sorption for most elements at pH 3–7 except the alkali metals. Direct INAA on the sorbent allows determination of Au, Ba, Cd, Co, Cr, Cu, Eu, Fe, Hg, In, La, Mn, Sc, Sr and V.

The most commonly used inorganic exchanger is HAP. The material is prepared, crushed and sieved and then packed into a column as with an exchange resin. The key feature of HAP is its ability to absorb Na strongly. Thus by passing seawater through such a column, the interfering Na is removed. Other chemically modified exchangers have been used for preconcentration in special circumstances.

\subsection*{4.3.2.4 Solvent Extraction}

This method like coprecipitation or scavenging has the advantage of rapidity and simplicity. Usually, the trace metals are extracted as chelates and the method simply requires the water sample to be shaken with the chelate in an immiscible organic solvent (usually CCl\textsubscript{4} or CHCl\textsubscript{3}). The metal reacts with the chelate and the metal chelate is then extracted into the organic phase. APDC and sodium diethylthiocarbamate (NaDDC) are the most widely used chelating agents. Extractions based on both these agents are pH-dependent so that the elements extracted can be controlled by controlling the pH of the water sample. Following the extraction, the organic solution may be subjected to INAA or sometimes a back extraction is performed so that the extracted metals are back extracted into an aqueous phase for irradiation.

\subsection*{4.4 Postirradiation Procedures: Radiochemical Neutron Activation Analysis}

It was argued at the beginning of this article that a major advantage of NAA over other analytical techniques was the possibility of chemical separation following irradiation (RNAA) by which contamination problems were eliminated. Unfortunately, with water samples, RNAA is not so advantageous. This is partly due to the limited volume of water and neutron dose that can be used in the irradiation, usually resulting in poor DLs even after chemical separation unless inordinately long counting times are used. Additionally, the presence of Br, Cl and Na, particularly for seawater samples, makes sample handling immediately after irradiation very difficult and also creates problems for the determination of short-lived elements. Thus RNAA is much less used for water analysis than for solid environmental samples.

The majority of postirradiation separations are based on either ion exchange or solvent extraction. A method that is commonly used is to pass the irradiated water through a column of HAP to remove (mainly) $^{24}\text{Na}$, which is often the most active nuclide present a few hours
after irradiation. This one-step procedure may then allow many of the other elements to be determined directly. Other inorganic exchangers have been investigated for selective removal of specific nuclides, with variable success. Conventional anion exchange resins are the most commonly used exchangers where chromatographic or group separations are required. For solvent extraction, extraction of chelates (PDC, in particular) is used with extraction into a number of solvents (CCl₄, CHCl₃, methyl isobutyl ketone (MIBK)).

Coprecipitation is occasionally used, as in the determination of As, Mo, Sb and Se, coprecipitated with Bi₂S₃. Substoichiometric isotope dilution analysis has also occasionally been used (determination of Cr). Finally, iodine is sometimes determined in irradiated water by isotope exchange. Here, irradiated water is shaken with a solution of iodine in CCl₄ when some 95% of the active iodine present in the water can be exchanged and then determined by counting an aliquot of CCl₄.

4.5 Biomonitoring and Hydrological Studies Using Neutron Activation Analysis

Monitoring the marine environment is one of the most difficult but most essential tasks in environmental studies. One method of monitoring is to analyze plant or animal tissues which are known to incorporate or concentrate pollutant elements. These materials are more amenable to INAA than the water itself but reflect the marine conditions. An example of this is the brown algae which inhabit most of the world’s coastal seas and show an affinity for a number of pollutants, such as Ag, As and Sr, and levels of many other trace elements, reflecting the waters they inhabit. They have been shown to be useful as monitors of trace elements in coastal waters.

Other marine plants are also useful in this context such as certain phanerogams. Some 43 trace elements have been determined in this plant by INAA, and comparisons between those growing in polluted and unpolluted areas reveal that the plant can be used to assess levels of pollution provided sampling is careful. In addition, these plants concentrate elements known for their biotoxicity from seawater and so can be used as indicators of this type of pollution.

The levels of As in drinking water have also been assessed by analysis of toenail clippings using NAA. It was found that a 10-fold increase in the concentration of As in the water led to about a twofold increase in toenail As. Thus, toenail As levels could be used to assess As levels in water of a particular region.

NAA has begun to play a part in hydrological studies in recent years. In the past, radioactive tracers were introduced into aqueous systems to study the behavior of large bodies of water, necessitating the use of large quantities of long-lived nuclides. Fears over potential contamination of the environment have led to the use of activable tracers instead. Here, an ordinary stable element but one not present in the water, is introduced. At a later time, the water is sampled, treated in a manner previously discussed and then activated. Measurements of induced activity indicate dispersal and other properties of the element and, hence, information on the water system itself.

5 ANALYSIS OF AIR PARTICULATES

5.1 Introduction

The analysis of the air constitutes the second major area of environmental analysis, along with that of water. The importance of air arises from its fundamental role in the existence of all living things. The air we breathe is essentially a mixture of gases with suspended solid particles and liquid droplets which are referred to as aerosols. NAA of air is essentially confined to the analysis of the suspended particulate matter. Although this may seem a very restricted role for NAA, the position of particulate matter in human health is currently regarded as one of the most serious environmental problems. There is particular concern regarding particles with aerodynamic diameters less than 10 µm, the so-called PM10. The IAEA began a global coordinated research program (CRP) in this area in 1992 and a report of the work has been issued. A review of this whole area and methods of determining compliance with current United States air quality standards for suspended particles has also appeared. An earlier review of the role of activation techniques in the analysis of aerosols also emphasized the importance of these particles.

5.2 Particulate Matter: Sources, Composition and Inhalation

The particulate matter found in air covers a wide range of sizes from about 100 µm down to about 0.01 µm diameter; however, the most important size range with respect to human health is that fraction < 10 µm diameter. This range is further subdivided into those particles between 0.08 µm and ~2 µm, which constitute the fine particle size fraction and those between ~2 µm and 10 µm which constitute the coarse particle size fraction. The majority of fine particles are of anthropogenic origin whereas the majority of coarse particles are of geological origin. Many schemes for sampling the air allow separation of these two fractions. The main sources of PM10 are shown in Table 3. The actual fraction of each of these components present in PM10 at a given site will be
strongly dependent on the source and it is possible to classify and identify sources of PM10 from the relative values of these fractions.

The reason for the interest in PM10 is that these represent the inhalable fraction of particulates since most particles larger than 10 µm are removed in the mouth or nose and so do not enter further into the body. Up to 60% of particles < 10 µm diameter may be deposited in the lungs. The health implications lie in the fact that these particles are contaminated by a wide range of elements and compounds, including toxic and carcinogenic ones. In addition, Si particles may result in lung damage even at low levels.

### 5.3 Sampling

The majority of environmental air sampling involves aerosol collection and the most widely used methods of collection are by filtration and impingement. Filtration is simple and provides sufficient material for subsequent NAA. A basic filtration unit consists of a filter holder, filter, an air mover (pump) and a flow-rate meter. Uniform flow of air across the filter is desirable since measurements of element concentrations are nearly always made directly on the filter. Accurate measurement of flow rate is also important in order to determine the total volume of air from which the sample was collected.

A wide variety of filter media are available but the two types most routinely used for environmental sampling are fibrous filters (cellulose paper or glass fiber mainly) and membrane filters (gel-type or nulepore). Cellulose papers are relatively cheap and robust but suffer from variability in collection efficiency. Nevertheless, for the rapid collection of sufficient material for an analysis they are quite adequate. Glass fiber filters have more uniform collection efficiencies and tend to collect more material at the surface of the filter but may give rise to high blank values for some elements.

Membrane filters are quite different in construction from fibrous filters but the most significant difference to the fibrous type is that the pore size is both controllable from fibrous filters but the most significant difference to

which is some form of obstruction. Particles carried in the airstream then collide forcibly with the obstruction and tend to collect on it. The collection efficiency is usually increased by attaching a “sticky” film to the surface of the obstruction such as a film coated with petroleum jelly. The main use of impingers is the ability to collect fractions of different particle size so that the range of particle sizes associated with the majority of the airborne elements can be determined. The major disadvantage of impingement devices, however, is the relatively small mass of material that can be collected. The cascading impactor is perhaps the most useful design of impingement equipment. It consists of a series of stages, each of which collects successively smaller particle fractions.

Kist et al.\(^{(52)}\) have described a sampling system for the small-size particles (<0.1 µm) and vapor-gas phases involving the use of very thin polyethylene films placed directly in the atmosphere. Various configurations were investigated and data indicated the potential for trapping submicron and vapor-gas aerosol phases.

### 5.4 Measurements

In the case of particulate matter collected alone, e.g. from an impaction collector, the material can be packed directly into cleaned polyethylene irradiation vials or compressed into a pellet first. For filters, the filters plus deposit may be folded and then packed into the irradiation vials. Even better is to compress the filter into a pellet which gives improved geometry for both irradiation and counting. Some filters are brittle and may crumble whilst being handled with possible loss of some of the deposit. Flexibility can sometimes be improved by exposure to acetone. For long irradiations, aluminum or silica may replace polyethylene which may become brittle after exposure to a high neutron fluence. Standards are usually prepared by pipetting accurate volumes of solution containing known concentrations of the elements under investigation onto filter discs and then after drying, treating them the same as the samples. A blank correction is always required when any type of filter disc is used since these always contain measurable levels of some trace elements, requiring a correction to the analyzed sample data. For the usual comparator method of INAA, suitable standards are required (either a single multielement standard, frequently a suitable SRM, or a series of filter standards containing only a single element).

Most of the trace elements in air particulate samples can be determined by INAA. This is particularly true for aerosols collected on organic filters. As discussed earlier, a major fraction of any aerosol will be organic matter, carbon, sulfate, nitrate or ammonium, none of which produce significant gamma activity. The inorganic fraction, mainly consisting of the oxides of Ca, Fe, Si and Mg, plus P and Cl again produce low or short-lived activities. Sodium and bromine can be a problem in some marine aerosols and this may require a delay in counting until the \(^{24}\text{Na}\) activity has decayed to an acceptable level, usually a few days after irradiation. Such a delay time precludes the analysis of any short-lived trace elements by this technique. In general, two irradiations are carried out as for most other types of environmental sample. A short irradiation (1–5 min duration depending on the available neutron flux) uses a rabbit system for the short-lived nuclides of Al, Ca, Cl, Cr, Cu, Mg, Na and V. This may also include CINAA for the determination of the very short-lived nuclides (<10 s) \(^{38}\text{mCl}\), \(^{77}\text{mSe}\), \(^{185}\text{mW}\) and \(^{207}\text{mPb}\). These are then followed by a long irradiation (2–8 h, again depending on the flux) and several counting periods at different decay times for the remaining long-lived elements. In this way some 33 elements (Al, As, Ba, Br, Ca, Ce, Cl, Co, Cr, Cs, Cu, Eu, Fe, Hf, Hg, K, La, Mg, Mn, Mo, Na, Pb, Rb, Sc, Se, Sm, Sn, Sr, V, W, Zn and Zr) can be determined with DLs ranging from \(4 \times 10^{-4} \text{ng m}^{-3}\) for Eu to \(30 \text{ng m}^{-3}\) for Ca and Cl, based on filtering 1000 m\(^3\) of air and irradiations with a flux of \(\sim 2 \times 10^{17} \text{nm}^{-2} \text{s}^{-1}\). A more complete set of DLs is given by Kolthoff et al.\(^{(53)}\)

These data are based on the normal multielement comparator technique. Some data have also been published based on the single comparator method which reduces the analysis time of the standards considerably. It has also been shown that the \(k_0\) method gives reliable results for suitable air particulate reference materials and has been used in some air pollution studies. A few more elements (Ag, Au, F, In, Ta, Th and U) are better determined by ENAA. Also, Landsberger and Wu\(^{(54)}\) showed that ENAA in conjunction with a Compton suppression \(\gamma\)-ray detection system gave improved DLs for As, Cd, I, Mo, Sb, Si, and U, with a particularly low DL for iodine. Finally, we have already mentioned that F is probably best determined by the \(^{19}\text{F(n,}\alpha)^{16}\text{N}\) reaction using 6 MeV neutrons from an accelerator in conjunction with a rabbit system.\(^{(29)}\)

The use of low-energy photon spectrometry (LEPS) i.e. photons in the range 50–200 keV has also been investigated for use with both INAA and ENAA. The technique, however, does not markedly add to the list of elements that can be determined using INAA beyond the lanthanides Lu, Sm, Tm and Yb and an advantage for the determination of Cu. In combination with ENAA, it improves the sensitivity for the determination of Br, Co, In, Sb and V.

FNAA plays a minor role in air particulate analysis. In general, it is confined to the determination of the matrix elements (Al, Ca, Cl, Fe, Mg, Mn, Si and Ti). In a few laboratories where high fluxes of 14 MeV neutrons are available (\(\sim 5 \times 10^{12} \text{n s}^{-1}\)) it is possible to determine
a number of trace elements although, again, the range compared with INAA and ENAA is not extended and the small sample weight mitigates against low DLs.

RNAA also plays little part in air particulate analysis. This is partly due to the fact that monitoring air pollution requires the analysis of large numbers of samples fairly rapidly but also due to the problems of sample size and dissolution.

Accuracy and precision are problems in any type of analysis. For INAA, the problems associated with the technique are well known and in most circumstances lead to a precision of $\pm 1-2\%$. For air particulate analysis, the largest error probably arises from the inhomogeneity of the sample; however, as long as the entire sample is subjected to analysis, this should not detract from the normal precision of the technique. Kist et al. revealed differences in the concentration of elements such as Au, Br, Cl, Hg and W determined by their passive absorption method compared with samples obtained by the standard filtering methods. This was ascribed to the fact that these elements exist in a thin particulate or a vapor-gas phase which are only sampled with poor efficiency by the use of standard filters.

5.5 Applications

5.5.1 Direct Methods of Analysis

A large number of studies of air pollution and related studies have certainly been undertaken since about 1985. The majority of these apply to the monitoring of the air in specific urban areas with some data from adjoining rural areas to provide a comparison. Alternatively, a number of studies have also been concerned with the analysis of the emissions in the neighborhood of incinerators, smelters and power stations since these can be the sources of pollutants into the local atmosphere. Equally, levels of pollutants in indoor public areas due to, say, tobacco smoking have become of concern. Analysis of filter samples of indoor air polluted by tobacco smoke using an ENAA technique revealed elevated levels of As, Cd and Sb, with consequential potential health risks beyond those normally associated with passive smoking.

5.5.2 Indirect Methods of Analysis

Monitoring the ambient air by the methods discussed above has limitations, on both a geographical and a temporal scale. These are due to the necessity of setting up monitoring stations in suitable areas, which are expensive in themselves, and then the necessity for analyzing the samples collected. Such monitoring stations are not really suitable for covering wide geographical areas, particularly if remote areas with difficult accessibility are involved. Also, studies over a long time period (several years) can involve the analysis of a large number of samples, even from one station.

In these circumstances, another approach is taken, that of indirect monitoring. The majority of such monitoring usually involves sampling various types of plant materials which can retain the elements deposited on them from the atmosphere and thus act as monitors of the atmosphere in which they are growing. Such materials are referred to as biomonitors. Other, nonorganic materials such as snow have also been used as accumulators of atmospherically deposited trace elements.

Lichens and mosses have almost invariably been used in air pollution studies since these plants absorb elements directly from the air because they lack root systems. They also concentrate and retain the elements absorbed. This is in contrast to vascular plants which take elements directly from the air and, more importantly, from the soils in which their roots grow. Hence, variations in element concentration cannot normally be directly correlated with changes in atmospheric concentration. An exception to this is the use of evergreen oak leaves to monitor vehicle pollution using both INAA and photon activation analysis (PAA) (for Pb). These leaves were shown to be very good monitors for air pollution studies, particularly for Pb and a few other elements (Ce, Co, Eu, Hf, Sb and Zn),
which were shown not to reach the leaves through the tree roots. There was good correlation between Pb on the leaves and the level in the air.

Generally, however, lichens and mosses have been used as biomonitors. One of the most comprehensive studies using mosses was that by Steinnes et al.\(^{(59)}\) Here a specific moss was collected from over 500 sites throughout Norway and the moss samples subjected to INAA, with some 22 elements determined. A further four elements were determined by flame AAS. The data from these studies allowed different sources of pollution to be identified varying from long-range atmospheric transport of pollutants from other parts of Europe to local sources within Norway. There was also an indication of atmospheric transport from the marine environment. Similar studies by Sloof and Wolterbeek based on lichens collected in the Netherlands were used to create geographical concentration patterns and to estimate the sources of pollution.\(^{(60)}\) Analysis of lichens and mosses by INAA has also been used to investigate pollution around industrial plants such as smelters.

A more unusual example of indirect monitoring is that based on the analysis of snow.\(^{(61)}\) The method is based on the fact that snow scavenges particulates from the air whilst larger particles sink into the snow and are immobilized in it. Samples of melted snow from the Montreal area of Canada were analyzed by INAA allowing enrichment factors to be determined and thus allocated to natural or anthropogenic sources.

### 6 ANALYSIS OF SOIL, SEDIMENTS AND COAL

#### 6.1 Soil

Considering the importance of soil for the production of food, there has not been a vast number of analyses by either INAA or RNAA. For INAA it is usual to perform a short and a long irradiation, as in most areas of environmental analysis, and possibly two counting periods following the long irradiation. This results in the determination of up to 24 elements (Al, Ba, Br, Ce, Co, Cr, Cs, Dy, Eu, Fe, Hf, La, Lu, Mn, Na, Rb, Sb, Sc, Sm, Tb, Th, V, Yb and Zn) in most soils and a further 16 (As, Au, Ca, Cl, Ho, I, K, Mg, Nd, Sr, Ta, Ti, Tm, U, W and Zr) in many soils. This number is augmented by nine more elements (Ag, Cd, Gd, In, Ir, Mo, Ni, Pd and Sn) by use of ENAA although, again, a few of the elements determined by INAA are better determined by ENAA. Further elements such as Hg and Se can be determined by RNAA but this technique has not been widely used for soils.

A number of soil and sediment SRMs are available to act as multielement standards or as reference materials, with some having quite high concentrations of several trace elements. These are often suitable as standards in the analysis of soils and sediments polluted by heavy metals.

Soils have also been analyzed in attempts to study the mobility of heavy trace metals through them. This is of particular concern where sewage sludge, often containing high concentrations of heavy metals has been used as fertilizer, a growing practice in many countries. The potential mobility of these metals in soils is of concern and has been investigated using both INAA and ICPS (inductively coupled plasma spectroscopy). INAA is probably a better method owing to the presence of some metals that are located generally in minerals resistant to acid digestion and hence give low readings by the ICPS technique. The data indicate that, not surprisingly, different metals have different mobilities but that significant amounts of Cd, Cu, Hg and Zn remain in the topsoil up to 15 years after application of the sludge.\(^{(62)}\)

Regional surveys of surface soils have also been carried out using INAA as well as other analytical techniques in order to construct accurate geochemical databases for environmental, agricultural and related purposes. Obviously, such surveys require the analysis of large numbers of samples for which INAA is admirably suited.\(^{(63)}\) Similarly, baseline element concentrations have been determined for soils and some associated vegetation in a given region with the aim of investigating landscape patterns of the elements. Additionally, soils have been used as pollution monitors in regions where they are subject to potentially high concentrations of toxic elements.

A number of studies using INAA have also investigated the uptake and concentration of heavy metals by plants growing in normal or contaminated soils. This is of concern where plant material for human consumption is grown. An example was the concern for the levels of Cd in cabbages grown domestically in the southwest of England when the levels of Cd in the soil were found to be several times the local background level.

#### 6.2 Sediments

By sediments we mean the material deposited at the bottoms of lakes, rivers, estuaries and seas. The techniques and elements that can be determined by INAA are very similar to those discussed for soils. In sediment analysis, however, a much greater emphasis is placed on determining element concentrations in sediment cores. Core samples are often obtained using a simple plastic tube, 2–5 cm diameter and up to a meter in length. The tube
is inserted into the sediment to obtain the core which can later be extruded from the tube. This core is then usually cut into sections (often 5 or 10 cm in length but shorter lengths for greater detail). Core sections, after drying (freeze drying preferred) and pulverizing can then be packaged for NAA. INAA, ENAA and FNAA have all been used to analyze sediment cores.

The core is essentially a historical record of the sediment with the age of the sediment increasing down the core; each cut segment then represents a specific time zone. Analyzing the segments reveals changes in the concentration of the elements with time and may reflect particular events in the history of the region. The total length of time represented by a single core obviously depends on the sedimentation rate, which itself may vary with time. A plot of change in concentration with core depth is known as a concentration–depth profile. In some cases the concentration–depth profile may reveal the sedimentation rate if it is assumed to be constant. Sodium concentration–depth profiles may reflect the change of sediment origin from lacustrine through brackish (possibly estuarine) and possibly even to marine for sediments found close to the sea. Cores taken from the sea bed adjacent to the outflow of a major river such as the Amazon or the Mississippi can distinguish the river sediments from those of marine origin and so can be used to investigate the factors controlling the discharge of river sediments into the ocean.

A number of countries (e.g. Canada, South Africa, UK) have also used INAA to analyze large numbers of samples obtained from lake and river sediments from throughout the country concerned again to provide regional geochemical databases. These can help in the geochemical exploration for commercially viable mineral deposits and potentially useful regions can then be investigated in greater detail by geological investigation.

The method of activable tracers has also been used to investigate accretion, reworking and erosion of sediments. Suitable tracers are certain rare earth elements (Dy and Sm) and in one case a Cs-saturated phlogopite (a form of mica with exchangeable K) where the Cs replaced the K of the phlogopite. In all cases the tracer is applied to the sediment. After a given period of time (ranging from days to years), the sediment is sampled and after activating the tracer, its concentration can be determined and used to investigate changes in the sediment.

Finally, studies of the transport and ultimate fate of pollutants can be studied by examining sediments from lakes or rivers. Analyses of such sediments is particularly useful for following the transport and ultimate fate of fertilizers washed out of fields and into rivers and lakes. Fertilizers of phosphate origin tend to have relatively high concentrations of the rare earth elements and this will result in increases of these elements in the lake or river sediments. INAA is a very sensitive method for the determination of most of the rare earths usually making it the preferred method in this type of study. Toxic elements such as As have been determined by RNAA in high concentrations in lake sediments as a result of the use of arsenite pesticides sprayed on to adjacent agricultural areas.

6.3 Coal

NAA has been widely used in coal analysis, much of it directed towards on-line analysis of bulk coal samples prior to their use in power or conversion (to liquid fuel or gas) plants. The other role of NAA in coal science is in the investigation of trace element concentrations and patterns.

Trace and minor element analysis of coal usually employs a short and long irradiation strategy, allowing for the determination of about 38 elements (Al, Ag, As, Ba, Cr, Ca, Ce, Cl, Co, Cr, Cs, Dy, Eu, Fe, Hf, I, K, La, Lu, Mg, Mn, Na, Nd, Rb, S, Sb, Sc, Se, Sm, Ta, Tb, Ti, Tl, U, V, W, Yb and Zn). In addition, B is sometimes determined by PGNAA. Coal SRMs are available to act as both multielement standards in INAA or to provide checks on the accuracy of analyses using other standards. Such analyses can serve a number of purposes.

One of these involves exploration and mining of coal where the trace element composition has been used to try to “fingerprint” coal seams. Most of these attempts, however, have not proved commercially viable owing to the large variations of trace element patterns within a given seam. More hopeful is the fingerprinting of certain formations that enclose a given seam.

Of more importance, however, is the use of trace element data to investigate the fate of volatile or more or less toxic elements when coal is burnt. Trace elements in coals might be expected to follow the crustal abundance of such elements. This is found to be the case for many of the elements although some such as As, Br, Cd, I, Mo, Pb, S, Sb and Se are significantly enriched. Levels of S vary widely in coals and, because of its crucial role in the production of acid rain, levels have to be carefully monitored.

The combustion of coal releases significant amounts of trace elements either in the form of gaseous discharge (Br, Cl, I, S and Se) or as fly ash, particulate matter of varying dimensions, to the atmosphere. These releases are then studied as part of air pollution monitoring, as discussed in section 5 of this article.

The rest of the trace elements not released to the atmosphere are retained in the ash that remains at the end of combustion. It is found that most nonvolatile elements are considerably concentrated in the ash. The total ash formed depends on the initial inorganic (mainly...
The sources most generally used are 252Cf and 241Am/Be. These power or maintenance and having long useful lifetimes. Being physically small, rugged, not requiring any external tope sources offer many advantages over accelerators, which are capable of producing rapid results. Also, radioactivity induced in the coal by neutron irradiation is both short-lived and negligible. Coal analysis in this context is used to determine the ash (from the concentrations of Al, Fe and Si), sulfur, nitrogen (important for its role in affecting catalysis in coal conversion) and chlorine (high chlorine coals cause boiler corrosion) contents of coal along with its calorific value. The latter is not determined directly but is based on the carbon content of the coal.

At present, the favored approach to on-line coal analysis is based on PGNAA. A fast neutron source (either isotope- or accelerator-based) is used and the neutrons thermalized within the coal to allow neutron capture necessary for PGNAA. For on-line situations radioisotope sources offer many advantages over accelerators, being physically small, rugged, not requiring any external power or maintenance and having long useful lifetimes. The sources most generally used are 252Cf and 241Am/Be. Unfortunately, the measured intensity of any capture γ-ray peak is not directly proportional to the element concentration as it also depends on the thermal neutron flux in the sample, which is itself dependent on the concentrations of all the elements in the sample and, in particular, small concentrations of B or Cl. On the other hand, the ratio of one capture γ-ray peak area to that of another is directly proportional to the ratio of the elemental concentrations. Therefore, if one capture γ-ray-producing element can be absolutely determined by a separate technique, a quantitative assay of all the other capture γ-ray producing elements can be made. Fortunately, this is possible in the case of hydrogen whose absolute determination can be made based on the measurement of the epithermal neutron flux escaping from the coal. This then allows for the determination of Al, C, Cl, Fe, N, S and Si by the peak ratioing technique.

Two problems still remain with on-line analysis based only on PGNAA. The first is that although C can be determined by detection of the prompt γ-rays, the method is severely limited by the small (n,γ) cross-section, so that the precision of the determination is poor. The second and more important problem is that PGNAA does not allow for the determination of O because its capture cross-section is extremely small and detection of subsequent γ-rays is almost impossible. Thus determination of O is only possible by difference, which involves the determination of the concentration of all the other major elements and the difference from 100% is assumed to be oxygen. This is the method that must be used in all other techniques for coal analysis.

Both problems are solved by the use of inelastic scattering reactions to produce γ-ray peaks. Here a 241Am/Be source must be used because of its ability to excite more noncapture reactions than 252Cf. Thus, C is determined from the 4.43 MeV γ-rays resulting from the 12C(n,γ) inelastic reaction. Oxygen is determined indirectly using the ratio of C to O peak areas produced in the inelastic scattering reactions on the two elements (6.13 MeV γ-ray from 16O(n,γ)). Since carbon can be determined either by PGNAA or absolutely using the inelastic scattering peak (to an accuracy of ±10%), this gives a method for the determination of oxygen. The disadvantage is that large expensive NaI(Tl) (thallium-activated sodium iodide detector) crystals must be used, which are also susceptible to vibration and thermal shock making them unsuitable for on-line purposes.

### 7 ROLE OF NEUTRON ACTIVATION ANALYSIS IN SPECIATION STUDIES

#### 7.1 Introduction

An important aspect of the analysis of trace elements in environmental samples is that of speciation. Speciation analysis can be defined as the concentration of an element in each of the physicochemical forms present in the system and which together represent the total concentration of that element. For example, natural waters usually contain some particulate or colloidal material so that a particular element may be present in solution or bound to the particles or colloids. A similar situation exists for other environmental samples such as air, where we have already seen that particulate matter is present, and in biological systems. The presence of different species (maybe in different oxidation states) of an element will affect a number of environmental parameters, such as its mobility, transport, bioavailability and toxicity.

NAA by itself cannot distinguish between the various species in which the element may be found; however, in combination with other analytical techniques it may be used very effectively in speciation analysis. The most important of these other analytical techniques are various separation methods which bring about the isolation of the respective fractions or forms which can then each be analyzed by the available NAA techniques.
7.2 Speciation of Elements in Water

There is a gradation in size between simple molecules present in solution and macroscopic particles rather than abrupt changes. It is important, therefore, that the method adopted for size fractionation does not itself disturb the original distribution. Size fractionation methods based on both filtration and ultrafiltration are commonly applied. For ultrafiltration, where the aim is to isolate the low-molecular-weight (low-MW) species, dialysis, the use of hollow-fiber cartridges or a series of ultrafilter membranes are usually the preferred methods. Hollow-fiber cartridges have the advantage that the species do not absorb on the fibers to any great extent. Cartridges with MW cut-off of 10^3, 10^4 or 10^5 are simply placed in the water and the species of mass below the particular MW cut-off are filtered through. Similarly, a series of filters and ultrafilters may be used to separate both larger, suspended particles and then successive MW fractions down to as low as MW 500. This ultrafiltrate can then be collected directly in polythene irradiation vials along with the the solid on the filter for INAA. Alternatively, a polythene container is used to collect the filtrates if RNAA is necessary. Analysis by INAA can give information for up to about 40 elements in many cases. Thus, it is possible to show the major forms in which these elements exist in water, e.g. alkali metals occur mainly as free cations, Al, Au, Sb, U and V mainly as hydroxy complexes whilst other elements such as Co, Cr, the lanthanides, Ni and Zn tend to form soluble organic and inorganic complexes. In addition, the size distribution pattern of a large number of elements can be readily investigated.

Water containing fulvic and humic acids (complex organic material) would be expected to give rise to organic complexes of several elements. One way to investigate such complexation would be to decompose the organic matter prior to ultrafiltration so that the dissolved trace elements are collected in the filtrate. The filtrate is dried to form a solid and both this and the solid collected on the filter are irradiated and elements determined by INAA. In this way, a crude estimation can be made of the trace elements present in the particulate matter and those present in the vapor-gas phase. Based on such experiments it was concluded that Au, Br, Cl, Cr, Cs, Fe, K, La, Mn, Se and Sm are found in the particulate fraction whereas As, Hg, Sb and Zn occur mainly in the vapor-gas phase.

For elements such as As, Cr and Sb, where their toxicity and biological activity depend on their oxidation state it is important to differentiate between species in different oxidation states. In order to do this some form of chemical separation is essential. We have already referred to the possible separation of As(III)/As(V) and Sb(III)/Sb(V) on MgO (section 4.3). The oxidation states of Sb can also be separately determined by INAA by use of the fact that only Sb(III) is extracted into a chloroform solution of APDC. Similarly, As(V) may be determined by its complexation with molybdate followed by coprecipitation with tetraphenylphosphonium chloride, with any As(III) present first removed with dibenzylthiocarbamate. Finally, Cr(III) and Cr(VI) can be separated based on the variation of the coprecipitation yields with Pb(PDC)₂ as a function of pH, with Cr(VI) coprecipitated at pH 4.0 but Cr(III) only at pH 9. INAA of the precipitate thus yields the distribution of either species directly. Similarly, iodide and iodate speciation in water can be determined following preconcentration on bismuth thionolide. Following irradiation of the precipitate, kinetic differences are exploited in the isotopic exchange of iodide and iodate with iodine in chloroform solution, since the isotopic exchange of iodide occurs almost instantaneously but that for iodate is very slow.

7.3 Speciation of Elements in the Atmosphere

One method that has been used is based on the analysis of rain water. The rain water is filtered through a membrane to collect the solid particulate matter whilst the soluble trace elements are collected in the filtrate. The filtrate is dried to form a solid and both this and the solid collected on the filter are irradiated and elements determined by INAA. In this way, a crude estimation can be made of the trace elements present in the particulate matter and those present in the vapor-gas phase. Based on such experiments it was concluded that Au, Br, Cl, Cr, Cs, Fe, K, La, Mn, Se and Sm are found in the particulate fraction whereas As, Hg, Sb and Zn occur mainly in the vapor-gas phase.

A method for separating particulate, inorganic and organic forms of iodine in the air has also been described. The particulate matter was collected in the usual way by filtration through a membrane filter. Inorganic iodine was collected by passing the air through two filters impregnated with lithium hydroxide and organic iodine in two beds of chemically treated activated charcoal. The filters or activated charcoal were then irradiated and ^125I counted. Results showed that almost 90% of the atmospheric iodine was in gaseous form in which the organic form dominated.

Nitroaromatic compounds (NACs) are important anthropogenic chemicals, which may enter all areas of the environment in significant amounts. Once there, they may be transformed, mainly via redox reactions. Most NACs and their transformation products are rather toxic, both in humans and ecosystems, and they are especially known for their carcinogenic potential. Thus, input and detrimental effects of NACs make environmental surveillance necessary, which in turn requires selective, sensitive, unbiased and robust methods suitable for the analysis of complex mixtures. These requirements are mainly fulfilled by the combination of an enrichment step with chromatographic separation and use of an appropriate detector. Official methods today use liquid–liquid extraction (LLE) or solid-phase extraction (SPE), followed by high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection, or gas chromatography (GC) with electron capture detection (ECD). These methods are widely established and have been thoroughly tested in interlaboratory comparisons. However, new methods for extraction, separation and detection are emerging, which are superior in terms of the required characteristics, and thus may replace the existing methods in the future. Both standard methods and new developments for the environmental analysis of NACs are discussed in this article. Regarding the references given, priority was given to the most recent developments, and thus about 70% of the cited literature is less than five years old.

1 INTRODUCTION

For decades, NACs have been among the most widely used anthropogenic chemicals. Nitration of aromatic compounds is one of the key industrial processes, since the nitro group offers a variety of further functionalizations. Thus NACs are used as solvents, pesticides, explosives and fragrances and are intermediates in the production of pharmaceuticals, dyes, polymers, whitening agents and photochemicals. Seventy NACs are currently listed as OECD (Organisation for Economic Co-operation and Development) high-production-volume chemicals, with a production of more than 1000 t per year in at least one member country. Of the parent compound nitrobenzene alone, 740,000 t were produced in the United States in 1994, mainly as a source for aniline. Emissions of NACs can occur during the production, the use and the disposal of the compounds. The Toxics Release Inventory of the United States Environmental Protection Agency (USEPA) estimates that the total emission of nitrobenzene to the environment in the United States was 320 t in 1997. In 53 of the USEPA Superfund Sites NACs are contaminants of concern. In addition to direct emissions, it has become obvious in recent years that NACs may also be formed in the atmosphere due to the reaction of nitrogen oxides with aromatics. This reaction is important both for polycyclic aromatic hydrocarbons (PAHs) to yield nitro-PAHs and for benzenes to yield mainly nitrated phenols.

There are hardly any naturally occurring NACs. One exception is aristolochic acid (Figure 1), which was used as a drug ingredient before its toxic effects were known. The molecular formulae of some important NACs are given in Figure 1. It can be seen that many compounds have more than one functional group governing their
behavior, therefore some of the compounds may also be covered in other articles.

Table 1 gives the CAS no. and some important properties of nitrobenzene, 2,4-dinitrotoluene and the compounds shown in Figure 1. As might be expected from the diversity of the compounds, their physicochemical properties differ widely. In general, NACs are electron-acceptor compounds and the acidity of aromatic acids is much increased because of the electron-withdrawing nitro group. The introduction of a nitro group does not significantly alter the water solubility of nonionogenic compounds. Many NACs are known to be highly toxic and are proven or suspected carcinogens. In contrast, the easily water-soluble nitrosulfonic acids do not show significant toxicity. However, their mobility and persistence in water make them possible drinking-water contaminants. A very common reaction in soil and water is the abiotic or biotic reduction of the nitro group to an amino group via three two-electron transfer steps. The corresponding anilines, which may be of even more environmental and toxicological concern, thus have to be considered in many cases. An extensive treatment on biodegradation of NACs can be found in the book by Spain. The complexity of wastewater generated during the manufacture of trinitrotoluene was demonstrated by Spanggord et al. Rosenblatt et al. showed the multitude of products from phototransformations of NACs, including for the first time nitrobenzoic acids resulting from photooxidation of the methyl group. Recently, these and other ionic compounds were found in groundwater and soil samples, which suggests other mechanisms in effect besides photooxidation. In summary, most NACs require monitoring due to their high production, their toxicity and their behavior in the environment.

2 OFFICIAL METHODS OF ANALYSIS

To the best of our knowledge, NACs are not included in legislative regulations as such. However, there might be regulations resulting from the use of specific NACs, e.g. as pesticides. These are not discussed further here since they are covered in other articles. Furthermore, the USEPA has issued health advisory levels for several explosive-related NACs, which are given by Tomkins in Explosives Analysis in the Environment. Despite the lack of general regulations, maximum NAC emissions from factories and contents in water and soil at former industrial sites might have been specified. For example, at the former ammunition plant in Stadtallendorf, Germany, remediation aims of 20–80 mg NAC per kg soil, depending on the proposed use of the area, were constituted by regional authorities.

Official methods of analysis for NACs are available for the determination of explosives, dinitroaniline pesticides and for a number of NACs in a general analytical scheme for semivolatile compounds. Table 2 briefly summarizes these methods.

As shown in Table 2 the official USEPA method 8030 has also been adopted for water analysis. Sample preparation involves a salting-out assisted solvent extraction with acetonitrile, as developed by Leggett et al. In the new draft method 8095 this procedure is replaced by SPE which needs considerably less organic solvent. The official method requires primary analysis on a C18 column with confirmation on a second CN column since a single-wavelength UV detector is used.

Both the German DIN method 38407-17 and the USEPA draft method for explosives utilize GC for separation. The USEPA method includes even very

thermolabile nitramines and is therefore carried out on a short, wide-bore column (6 m × 0.53 mm) of low polarity (DB$^\mathrm{m}$-1 or DB$^\mathrm{m*}$-5 or equivalents) for primary analysis and a mid-polar column (RTX$^\mathrm{m}$-200 or RTX$^\mathrm{m*}$-225 or equivalents) for confirmatory analysis. The DIN method also requires a confirmatory analysis on a column of different polarity, but the recommended columns have an internal diameter of 0.2–0.4 mm and a length of 20–60 m. Suggested stationary phases range in polarity from DB$^\mathrm{m}$-1 to DB$^\mathrm{m*}$-1701 or equivalents.

The standardized methods can help the practitioner in the fast establishment of a new method and are often required by regulatory bodies. The main advantage of these methods is the assurance of data quality by thorough testing and interlaboratory comparisons.\(^{14}\) However, it should be emphasized that their use also poses some problems. Usually, the standardization requires several years before being officially adopted. Considering the rapid developments in the area of instrumental analysis they therefore often demand the use of rather outdated methods or equipment. As an example, USEPA method 8030 for the analysis of nitroaromatic explosives in soil and water is discussed here. The processing of water samples requires the use of salting-out extraction with 175 mL acetonitrile per sample. Some 97% of the acetonitrile remains in the aqueous phase and has to be disposed of with the sample. Furthermore, the extraction is very time-consuming, requiring several extraction/back-extraction steps. Modern SPE methods are able to provide at least comparable extraction efficiencies with much less solvent and time consumption. For soil samples an 18 h acetonitrile extraction in an ultrasonic bath is used. Here it has already been shown that faster methods such as accelerated solvent extraction (ASE) or supercritical fluid extraction (SFE), which are rather easy to automate and consume little solvent, are applicable. Nevertheless, none of these methods are included in the new draft method of the USEPA. In the determination step a primary column with an internal diameter of 4.6 mm is recommended. Again, it has been known for a long time that 4- and even 3-mm columns can be used with almost all HPLC equipment, providing even better separation in many cases, with much less consumption of the mobile phase. Loadability of the smaller columns is lower but in general this is not a severe problem in environmental analysis. Detection is done with a single-wavelength UV detector at 254 nm. To confirm positive results therefore requires a second column of a different selectivity. However, in most HPLC laboratories nowadays a diode-array detector (DAD) is in use which allows the on-line confirmation of peak identity with the comparison of UV spectra. This of course requires much less time than a second run for the same sample. Because of the drawbacks of the official method, several method adjustments were recently published to improve its performance.\(^{15,16}\)

The USEPA method was selected as an example for outdated procedures because it is still in use worldwide.
but, as already mentioned here, the general problem exists for all standard methods.

3 SAMPLE PREPARATION

3.1 Water

3.1.1 Sampling and Storage
Water samples should be taken in precleaned brown-glass bottles. Bottles and stoppers should be rinsed several times with the sample on-site. Since some of the analytes are volatile the bottles should be filled completely, without leaving a headspace. Extraction of water samples should be done as soon as possible after sampling. If storage cannot be avoided the samples should be stored at temperatures below 4°C. Even then losses are possible with prolonged storage times. The loss is mainly due to microbial degradation, hence the stability is enhanced if growth of microorganisms is inhibited. For that purpose, sodium azide and mercury(II) chloride are mainly used, but the use of mercury salts is not recommended due to problems with the disposal of the samples after processing. A 1-mL portion of a saturated solution of sodium azide in water is sufficient to depress microbial activity in a 1-L sample.

3.1.2 Extraction
A brief overview of important characteristics of some extraction techniques for aqueous samples is given in Table 3. More detailed information can be found in the following sections and the cited literature.

Liquid–Liquid Extraction Several solvents are suitable for LLE of NACs. Most often, toluene (as in DIN 38407-17) and dichloromethane (as in USEPA method 625) are used. In general, the choice between the two is partly determined by the detection method. For GC/ECD, toluene has to be used, while for the GC/MS and HPLC methods, dichloromethane is preferred (for HPLC this is because solvent exchange is easier with the more volatile dichloromethane). In the DIN method the extraction is done with two portions of 20 mL toluene (with 10 min of shaking in a separatory funnel) for a water sample of 1 L after adjusting the sample pH to between 6 and 8. In contrast, the dichloromethane extraction is done after salting-out of the sample with 100 g sodium chloride (for 1 L water). It is then extracted three times with 50 mL dichloromethane. In both cases, the extracts are dried over anhydrous sodium sulfate, filtered and reduced in volume under reduced pressure. Alternatively, the approach of Leggett et al. (as used in the adaptation of USEPA method 8030 for water) might be used. They extracted with acetonitrile and achieved a phase separation between water and acetonitrile with the addition of high amounts of salt (see section 2). A general disadvantage of all LLE procedures is the use of rather high amounts of organic solvents, especially when more polar degradation products have to be included. An attractive further development in LLE is the use of a micro-extraction technique as described by Welsch and Block, who found satisfactory recoveries (>70%) for nitroaromatic explosives and reduction products with the use of only 4.5 mL methyl tert-butyl ether in a multiple extraction scheme. Limit of detection (LOD) values given were in the low parts per trillion (ppt) range for di- and trinitroaromatics and in the high ppt range for mononitroaromatics.

Solid-phase Extraction SPE has increasingly replaced LLE in the analysis of NACs in water over the last decade. This is due to the reduction in organic solvent use, the high recoveries obtained in many cases, the ease of sample clean-up and the possibility of coupling SPE on-line with chromatographic separation. SPE procedures are included in both the DIN method and the new USEPA draft method for NACs in water. In both cases a C18 phase is used for that purpose. As an example, the DIN method is described in more detail here. A 2-g sample of the solid phase (for 1 L sample volume) is conditioned with 15 mL of methanol and washed with 15 mL of water.

SPME, solid-phase microextraction.
The water sample is salted out with 100 g of sodium chloride per liter of sample and the pH is adjusted to between 6 and 8. The extraction is performed with a flow of about 16 mL min\(^{-1}\). Afterwards, residual water is blown off with nitrogen and the analytes eluted with 6 mL of ethyl acetate. If necessary, to achieve lower detection limits, the eluent is reduced in volume to 1 mL. C\(_{18}\) phases were described most often in experimental work carried out at the end of the 1980s and the beginning of the 1990s. However, their use in the analysis of NACs is already declining because of the commercial advent of polymeric phases, which offer higher capacities, a better retention of more polar compounds and enhanced pH stability, which is important for the analysis of degradation products. Styrene–divinylbenzene copolymers, which are available from most manufacturers of SPE materials, are mainly used for the extraction of NACs.\(^{19}\) The extraction can easily be automated, as has been shown for explosives,\(^{19,20}\) as well as for nitroaromatic pesticides.\(^{21}\) Solid phases in disk geometry allow higher flows than packed cartridges and have less susceptibility to clogging, which are distinct advantages, especially for the extraction of large volumes of aqueous samples. In a recent monitoring study for selected pesticides (including NACs) in groundwater, a flow of 30 mL min\(^{-1}\) was used without breakthrough of analytes or pressure increase due to clogging.\(^{22}\) Disk-type solid phases are already employed in the general USEPA method for performing SPE (SW 846/3535), and laboratories using cartridge types have to prove comparable performance.

An interesting new approach for the selective enrichment of NACs was described by Bucheli et al.\(^{23}\) It is based on the interaction between electron-deficient aromatic rings and electron-rich clay minerals, which leads to the formation of electron donor–acceptor (EDA) complexes. These are strongest for polynitroaromatics, while for mononitroaromatics they are less efficient than the previously mentioned polymeric phases. The method has been proved to be suitable for routine analysis and on-line SPE.

**Solid-phase Microextraction** SPME is a relatively new, solvent-free extraction method that so far has rarely been described for the enrichment of NACs from water. However, there are reports on the extraction of nitrophenols,\(^{24}\) dinitroaniline pesticides,\(^{25}\) and several explosives, including trinitrotoluene and DNT, in seawater.\(^{26}\) These reports have shown the potential of SPME, especially in conjunction with GC/MS. In general, SPME is still limited to GC separations in routine analysis and it requires the use of internal standards (preferably isotopically labeled ones) for accurate quantitation, because it is a nonequilibrium method.

### 3.2 Soil and Particulates

#### 3.2.1 Sampling and Storage

A thorough treatment of the representativeness of soil sampling for explosives analysis has been carried out by Tomkins. Explosives Analysis in the Environment.\(^{12}\) Briefly, a well-designed sampling plan is required to ensure the quality of spatially resolved information on contamination levels. Even inside a sample it is often difficult or impossible to obtain a homogeneous distribution of the analytes. Thus it is also important to make sure that a representative subsample is used for further analysis. Soil samples can be refrigerated without significant loss of analytes for several weeks but should be kept in the dark to prevent photodegradation.

For the sampling of particulates, high-volume air samplers are most frequently employed, which suck about 2000 m\(^3\) air through a filter. The choice of an appropriate filter type is crucial in proper sampling.\(^{27}\)

#### 3.2.2 Extraction

There is a wide range of methods available for the extraction of soil samples. The classical approach is either extraction at elevated temperatures in a Soxhlet apparatus or mechanical shaking of the solid with an appropriate solvent. More recently, these methods have been partly replaced by extraction in an ultrasonic bath. These three methods and the use of a homogenizer–sonicator were compared by Jenkins and Grant\(^{28}\) for the analysis of explosives in soil. They found extraction in an ultrasonic bath to be superior to the other methods. Lately, SFE and ASE have attracted considerable attention, and for some NACs there are applications for their use in extractions of solids. A brief overview of the important characteristics of some extraction techniques for solids is given in Table 4. More detailed information can be found in the following sections and the cited literature.

**Soxhlet Extraction** Even today, Soxhlet extraction is the standard method in many application areas, for example for the extraction of diesel emission particulates on filter paper.\(^{27}\) Several solvents are commonly used, such as diethylether, dichloromethane, cyclohexane, and toluene. Recoveries are high for many compounds, but the temperature must be carefully controlled because many nitroaromatics are thermolabile. The distinct disadvantages of the Soxhlet method are its very high solvent consumption, usually 100–500 mL per sample, and the long extraction times needed (up to 48 h is common). The time of each cycle varies between 15 and 30 min.

**Ultrasonic Treatment** Ultrasonic treatment for the extraction of nitro-aromatic explosives was thoroughly
investigated by Jenkins et al.,\textsuperscript{(28,29)} and shown to give reproducible results in an interlaboratory comparison.\textsuperscript{(30)} As a result of these studies, the use of an ultrasonic bath in soil extraction became mandatory in USEPA method 8330 for explosives. In this method a 2 g subsample is extracted with 10 mL aceto-nitrile for 18 h. The fine particles are then flocculated with a calcium chloride solution (concentration $= 5$ g L$^{-1}$). After 15 min settling time the sample is filtered through a 0.5 µm filter. An internal standard should be added to the extraction solvent. In this method, acetonitrile is chosen as the extractant because of its better solvation of the nitramines, while, for the NACs, methanol gave comparable results regarding extraction efficiency. For other NACs, ethyl acetate, ethanol and dichloromethane have also been used. A general advantage of the ultrasonication technique is the possibility of processing several samples at the same time. A disadvantage is that it is not well suited for automation.

**Accelerated Solvent Extraction** In the past few years accelerated extraction from solids at elevated pressures and temperatures has been employed in many fields. Surprisingly there was only one report in the open literature on the use of this method for NAC extraction.\textsuperscript{(31)} The authors compared six different extraction techniques for nitroaromatic explosives in real soil samples from a former ammunition plant. They found ASE with methanol to be comparable to standard methods in terms of extraction efficiency and reproducibility, but superior in terms of solvent consumption and extraction time. Saito and Yamaguchi\textsuperscript{(27)} expect ASE to replace both Soxhlet and ultrasonic extraction for the analysis of particulates in the future.

**Supercritical Fluid Extraction** In contrast to the more recently introduced ASE, SFE employs mainly CO$_2$ as the extracting medium. CO$_2$ is chosen because of its favorable critical parameters (i.e. critical pressure 74 bar, critical temperature 32°C) which help to keep it in the supercritical state. Lopez-Avila and Beckert prepared a thorough overview on the use of SFE in environmental analysis, including the extraction of 36 NACs from sand and a reference soil.\textsuperscript{(32)} In the last few years the influence of different modifiers on the extraction efficiency has been intensively investigated.\textsuperscript{(33–35)} For trinitrotoluene and trinitrobenzene Wuiecik and Seiber\textsuperscript{(34)} found the following conditions to be optimal: 5% methanol, 150 °C, 517 bar (7500 psi), 5 min static and 15 min dynamic extraction. Deuster et al.\textsuperscript{(35)} emphasized that direct addition of the liquid modifier to the sample was superior to the use of premixed CO$_2$/modifier. Toluene and acetoni-trile were comparable in enhancing the extraction efficiency of pure CO$_2$ for nine NACs, whereas methanol was less effective. The optimized conditions were: 2 mL modifier, 90 °C, 400 bar, 15 min static and 15 min dynamic extraction. SFE was also found to be suitable for the extraction of parathion and 4-nitrophenol from soil\textsuperscript{(36)} and it is assumed that SFE should be similarly suited to the analysis of nitro-PAHs.\textsuperscript{(27)}

4 METHODS WITHOUT ANALYTE SEPARATION AND IN SITU TECHNIQUES

#### 4.1 Chemical Methods

Numerous chemical reactions of NACs leading to colored products are described in the literature. Such reactions are the basis for spot tests, spraying reagents for thin-layer chromatography (TLC) and titration procedures. Several spot tests on NACs are described by Jungreis and Ben-Dor.\textsuperscript{(37)} The principles of the tests are: transformation of a polynitroaromatic with strong base to a highly colored Jackson–Meisenheimer anion or quinoidal form (Janovsky reaction); derivatization with phenylacetoni-trile in an alkaline dimethylformamide (DMF) medium to a blue- or yellow-colored addition product; formation of a charge-transfer complex with N,N-diethylaniline.

Of these, only the Janovsky reaction has so far been employed in environmental analysis. A procedure reported by Medary\textsuperscript{(38)} uses methanol as the extraction solvent for soil samples. The absorbance of the purple color produced by addition of sodium hydroxide to the soil extracts is measured at 516 nm and found to be directly proportional to the concentration of trinitrotoluene. The estimated detection limit of the method is 4–8 ppm.

The same reaction was utilized for a field-test kit for trinitrotoluene allowing semiquantitative measurements.\textsuperscript{(39)} To achieve this, small glass columns are filled
with a polystyrene-based anionic exchanger with a thin layer of a solid base (NaOH, CaO or MgO) on top. In the field, 5–50 mL of water or a methanolic soil extract is injected with a disposable syringe. The colored Jackson–Meisenheimer anions are formed in contact with the base and extracted with the anion exchanger. The length of the colored zone in the column differs depending on the amount of trinitrotoluene present. As might have been expected, there are a number of interferences, for example due to other organic or inorganic anions in varying concentrations.

The adaptation of the Janovsky reaction to an automated sequential injection system was recently reported for the rapid quantitative determination of TNT in soil.\(^{40}\) Acetone extracts of the soil samples were injected with a reagent solution of potassium hydroxide and sodium sulfite into a carrier stream (acetone/water 88/12). After a reaction time of 30 s the mixture was dispensed by the carrier through a flow cell of a spectrophotometer and the absorbance was measured at 470 nm. It was shown that the method is selective for TNT and had only little or no response to mono- and dinitroaromatic compounds. The detection limit was 0.5 \(\mu\)g mL\(^{-1}\) trinitrotoluene in solution.

Another possibility for a spot test is the facile reduction to the corresponding aromatic amines, which can subsequently be derivatized to form highly colored azo dyes.\(^{41}\) If the dyes are extracted with \(n\)-butanol a semiquantitative colorimetric or photometric measurement is possible.

The general advantage of such simple chemical methods is their quick and easy use in the field, which allows a sound selection of samples for further analysis. However, due to their low specificity and sensitivity, their use will be limited to investigations on sites where rather high concentrations of NACs are found.

### 4.2 Electrochemical Methods

Determination of NACs by electrochemical methods utilizes the reduction of the nitro group. Depending on the pH of a solution, the reduction leads to the corresponding hydroxylamino compounds or anilines, which require 4 e\(^-\) or 6 e\(^-\), respectively, for each nitro group. Thus polynitroaromatics in particular can be very sensitively detected, a technique which is also used in electrochemical detectors in HPLC (see section 5.2). With differential pulse polarography (DPP) and adsorptive accumulation methods, detection limits in the low \(\mu\)g L\(^{-1}\) range are achievable. Voltammetric methods have been intensively investigated for the determination of NACs, but there are few applications in environmental analysis. Recently, it was shown that with DPP tri-, di- and mononitrotoluenes can be distinguished due to their different reduction potentials.\(^{42}\) After minimizing the differences in reduction potentials of positional isomers, this method was used to establish a sum parameter for rapid determinations in process water from a treatment plant for contaminated soil. The principle of the method is shown in Figure 2. Firstly, the concentration of TNT is calculated from \(H_{SI}\) by comparison with a TNT standard \(H_{Pl}\). The contribution of this TNT concentration to SII is calculated and subtracted from the overall peak height to yield \(H_{SII}\), which gives the concentration of DNTs. The same procedure is repeated for SIII and the mononitrotoluene concentration is calculated from \(H_{SIII}\). Method validation with a standard HPLC method showed good agreement of the results.

![Figure 2 Voltammetric detection of nitrotoluenes. Reduction at different potentials allows quantification of tri-, di- and mononitrotoluenes. SI to SIII: sum peaks for tri-, di- and tri-, mono-, di- and trinitrotoluenes, respectively. \(H_{Pl}\) to \(H_{SI}\): peak height for tri-, di- and mononitrotoluenes, respectively. (Adapted from Weibels\(^{42}\) by permission of Görich & Weiershäuser, Marburg.)](image-url)
4.3 Immunoassays and Sensors

Immunochemical methods have been successfully used in biochemical and biomedical analysis for many years. In the last decade they have received increasing acceptance in environmental analysis. Enzyme-linked immunosorbent assays (ELISAs) are generally faster and less expensive than conventional analytical methods and require only simple equipment. They are highly specific and can be used without or only minimal sample clean-up and are therefore especially suited for field screening tests.

The procedure for a heterogeneous ELISA involves the following steps. First the surface of the test device, in most cases a microtiter plate coated with an analyte antibody, is incubated with the analyte solution and an analyte–enzyme conjugate. In a competitive reaction both can bind to the antibodies on the surface. After a specific reaction time, the system is washed to remove unbound molecules. In the next step the enzyme substrate is added, which is converted to a colored reaction product by the enzyme of the bound analyte–enzyme conjugate. The intensity of the color is inversely proportional to the concentration of the analyte and can be determined photometrically.

Several immunological assays have been developed for the determination of the explosive TNT. A strategy for the validation of commercially available immunoassay test kits is described by Krämer. Eck et al. reported the development of assays for 1,3-dinitroaromatic compounds. The limits of detection for 2,4-DNT, 2,6-DNT, 1,3,5-trinitrobenzene and TNT were 1 ng mL$^{-1}$. No cross-reactivity with mononitroaromatic compounds was observed. 4-Nitrophenol and monosubstituted 4-nitrophenols can be determined with an ELISA at levels as low as 0.2 ppb (parts per billion) in water samples without extraction and clean-up.

Keuchel et al. described the development of a sensitive and selective immunoassay and its application for screening of TNT in groundwater. The method has a detection range from 40 ppt to 10 ppm for TNT in water, while di- and mononitroaromatic compounds show cross-reactivities below 2%.

A rapid immunofiltration assay was developed especially for on-site testing, allowing the determination of TNT in water and soil samples within an assay time of about 6 min. The test shows a quantitative color response to concentrations ranging from 1 to 30 μg L$^{-1}$ TNT in water and 50–1000 μg kg$^{-1}$ TNT in soil.

Dosch et al. used a homogeneous apoenzyme reactivation immunoassay system (ARIS) for the detection of TNT with a LOD of 5 μg L$^{-1}$. The system is less sensitive than heterogeneous ELISA methods, but faster and more simple, because it does not require any washing step.

NACs and their biodegradation products can be bound covalently to the organic matter of the soil. These bound residues are nonextractable with organic solvents and are therefore not detectable with common analytical methods. For the quantitation of such residues, immunoassays can be extremely useful. A first example in the literature is the use of a sandwich immunoassay to detect bound trinitrophenyl residues in polluted soil samples after exhaustive Soxhlet extraction. The humic acid–analyte complex (bound NAC residue) is immobilized on the surface of the microtiter plate via nonspecific interactions with a basic protein. The bound trinitrophenyl fraction is then detected by a TNT-selective antibody. In the final step the bound TNT–antibody couples to an enzyme-labeled antibody. The color of the enzyme reaction is directly proportional to the amount of bound analyte.

Most immunoassays have been designed as highly specific methods with only minimal cross-reactivity. In screening tests, however, a high cross-reactivity is useful to detect the analyte, its metabolites and structurally related compounds. Broadening the antibody specificity offers the possibility of developing a group-specific assay for the analysis of 2,4,6-TNT, its precursors and metabolites in soils.

Quantitation of 1-nitropyrene, which is suspected to have a high mutagenic and carcinogenic potential, in diesel soot and urban aerosols with an ELISA was investigated by Fröschl et al. The cross-reactivities with several other NACs possibly present in air particulate matter were determined.

Numerous sensor systems for the detection of NACs, especially of trinitrotoluene, have been reported in the literature. Buttner et al. describe the development of an amperometric sensor for the selective in situ detection and quantification of TNT and other nitrated explosives in soils. Thermal decomposition of the contaminated soil samples by a platinum wire heater (900°C) produces volatile nitrogen–oxygen compounds which were detected with a sensitive amperometric gas sensor. The system has a detection limit of 0.5 mg kg$^{-1}$ for trinitrotoluene in soil.

An electrochemical sensor with rapid square-wave voltammetric scanning was used by Wang et al. for the continuous monitoring of TNT in natural waters with low ppb detection limits. Fast detection of nitro- and aminoaromatic compounds with an electrochemical sensor system based on cyclic voltammetry was reported by Krausa et al.

Several immunosensors have been developed for the detection of TNT on the basis of a competitive immunoassay (Shriver-Lake et al., Bart et al.). A comparison of the detection limits, the assay time and the run-to-run stability of different sensor system is given by Narang et al.
5 SEPARATION TECHNIQUES

The standard work on chromatographic methods for the separation of nitroaromatic and other explosives was published by Yinon and Zitrin in 1993. Because of their experience, mass spectrometric methods and forensic analysis are emphasized in the book, whereas there is only a brief chapter on environmental analysis.

5.1 Gas Chromatography

Despite the limited thermostability of many NACs, separations with GC are possible without derivatization for all nonionic compounds. GC in fact is very popular for the analysis of all kinds of NACs. The reasons are the high separation efficiency compared with liquid chromatography, the range of detectors, and the ease of "hyphenation", especially with mass spectrometry (MS). Furthermore, the presence of the nitro group in analytes does not require the use of special columns, thus nonpolar polydimethylsiloxanes are widely used. However, especially in explosives analysis, short wide-bore columns are often used to prevent thermodegradation on the column. Thus, for example, the USEPA draft method employs a low-polarity 6 m × 0.53 mm column for primary analysis. Besides, polynitroaromatics may be thermally degraded in the injector. Therefore the use of a filled liner is not recommended and the liner has to be replaced regularly. No single injection technique was found to be superior for all NACs. Methods in the literature comprise split, splitless, on-column and programmed temperature vaporizer (PTV) injection, depending on solvent type, sensitivity required and availability of instrumentation. If further functional groups are present, they will often determine the choice of column and injector. Yinon recommended the use of a cooled, temperature-programmable injector for the analysis of explosives, including DNTs and TNT, in water samples. Large-volume injection of water into a PTV was used by Müller et al. for the investigation of NACs. After evaporation of water and adsorption of the analytes from the gas phase, they are thermally desorbed in the PTV. An inherent disadvantage of this method is the very low injection rate due to the high enthalpy of vaporization of water, leading to prolonged analysis times.

A short overview of the most important GC detectors for NAC analysis is given in Table 5.

compounds and is thus suited for the analysis of NACs. It is especially useful in the investigation of parathion insecticides, since these contain both elements, but has also been used for the detection of nitro-PAHs in dichloromethane extracts of airborne particulates.

From the number of publications, ECD seems to be the most popular detection technique for NACs besides MS. This is due to the ease of use and low cost of the detector, which provides adequate selectivity in many cases. The rather high electron affinity of NACs allows a sensitive detection. In general, the sensitivity increases with the number of nitro groups in the compound. A general disadvantage observed by many authors is the limited linear range of the detector. Examples of the use of ECD from the recent literature are for the determination of nitroaromatic pesticides in groundwater and the analysis of nitroaromatic explosives in water samples. The use of ECD is demanded in DIN method 38407-17 and USEPA draft method 8095. The DIN method alternatively allows the use of a PND, and a splitting of the column effluent to provide simultaneous detection is recommended.

The highest selectivity towards nitro (and nitroso) groups is shown by TEA. Since it is not a generally known...
GC detection technique, its principle is described here briefly. After separation of the compounds the column effluent is pyrolyzed at 600–1000°C. The decomposition leads to the formation of NO₂, which is catalytically reduced to NO. After passing a cold trap to remove interfering pyrolysis products, it is oxidized with ozone and reduced to NO. After passing a cold trap to remove nitrogen dioxide is also favored, especially by Feltes et al. Loss of nitrogen dioxide is also favored, especially for nitrotoluenes, since a stable tropylium cation [M+ NUL] is formed. Nitrotoluenes are also a classical example of the “ortho-effect”, which often allows the distinction of ortho-isomers from meta- and para-isomers. In o-nitrotoluene, interaction between a methyl proton and an oxygen of the nitro group leads to the loss of a hydroxyl radical [M− 16]⁺ or, after rearrangement to the corresponding nitrite ester, nitrogen oxide [M− 30]⁺. Loss of nitrogen dioxide is also favored, especially for nitrotoluenes, since a stable tropylium cation [M− 46]⁺ can be formed. Nitrotoluene are also a classical example of the “ortho-effect”, which often allows the distinction of ortho-isomers from meta- and para-isomers. In o-nitrotoluene, interaction between a methyl proton and an oxygen of the nitro group leads to the loss of a hydroxyl radical [M− 16]⁺ or, after rearrangement to the corresponding nitrite ester, nitrogen oxide [M− 30]⁺.

The use of TEA for the analysis of explosives was thoroughly discussed by Yinon and Zitrin. Although TEA exhibits some unique features it is not widely used in environmental analysis. Probably this results from its high selectivity, which limits its use to nitro and nitroso compounds, and thus it is only available in specialized laboratories.

Maybe the most important detection technique in GC today, because of its general applicability along with its high selectivity, sensitivity and additional spectral information for compound identification or confirmation, is MS. With the standard EI ionization at 70 eV, radical cations are formed ([M+ 1]⁺) which subsequently lose an oxygen radical [M− 16]⁺ or, after rearrangement to the corresponding nitrite ester, nitrogen oxide [M− 30]⁺.

With chemical ionization, detection in negative ion mode is often used, since the formation of a radical anion is favored by the high electron affinity of NACs, especially in the case of polynitroaromatics. NCI allows more sensitive detection: a factor of 20 in single ion monitoring was reported for 2,6-DNT, and more than two orders of magnitude for 1-nitropyrene and 3-nitrofluoranthane. However, it yields much less fragmentation and is seldom used for quantitative analysis due to reproducibility problems.

In the authors’ laboratory the following method is used in routine analysis of water samples with GC/MS, though the enrichment step with dichloromethane will be replaced by a SPE method in the near future. As internal standards, the deuterated analogs 2-nitrotoluene-d7 and 2,4-DNT-d3 are spiked into each sample prior to extraction. The 500 mL sample of water is extracted three times, each with 40 mL dichloromethane, and the combined extracts are concentrated in a rotary evaporator at 40°C to about 1 mL and placed into 1.4 mL autosampler vials. If necessary for lower detection limits, the extract is further reduced in volume under a gentle stream of nitrogen. A 1 µL sample of the extract is injected on-column. A separation column with medium polarity is especially suitable since it allows a better separation of the DNT isomers than a nonpolar column. A typical separation is shown in Figure 3. For this separation DB™-1701 (or equivalent), 30 m × 0.25 mm, and 0.25 µm film thickness was used. The GC temperature was held at 40°C for 1 min, then raised at 10°C min⁻¹ to 230°C. The carrier gas was helium at 1.03 bar (15 psi) column head pressure, and detection done with electron ionization in SIM mode.

The use of deuterated standards in such analyses is highly recommended to allow compensation of analyte losses during sample preparation and of changes in ionization efficiencies. For this purpose, some deuterated NACs are commercially available (e.g. from Promochem, Wesel, Germany).

Even higher selectivity and (due to the enhanced signal-to-noise ratio) sensitivity is possible with the use of MS^n methods, mostly employing a triple–quadrupole instrument (allowing MS/MS, tandem MS or MS^3) or an ion-trap detector, which is in principle able to provide even higher dimensions in MS detection. However, practical reasons limit the use mostly to MS/MS/MS (or MS^3). Recent examples of the use of tandem MS in the analysis of NACs describe the analysis of nitro-PAHs in air and soil. In the former application the best MS conditions were found to be selection of the molecule ion in the first stage of the MS instrument and subsequent reaction monitoring with detection of NO₂⁻ at m/z 46.

Figure 3 GC/MS chromatogram (EI, SIM) of a NAC mixture. Peak assignment: 1, nitrobenzene; 2, 2-nitrotoluene-d7; 3, 2-nitrotoluene; 4, 3-nitrotoluene; 5, 4-nitrotoluene; 6, 2,6-DNT; 7, 1,3-dinitrobenzene; 8, 2,5-DNT; 9, 2,3-DNT; 10, 2,4-DNT-d3; 11, 2,4-DNT; 12, 3,5-DNT; 13, 3,4-DNT.
A new, very interesting approach for the determination of NACs in soil samples was introduced by Williams and Pappas. The1 They used ultrahigh-speed GC on 0.5 m capillary columns and subsequent detection with a surface acoustic wave detector after thermodesorption of the analytes from soil for separation and detection of trinitrotoluene and DNT isomers in less than 2 min. The method was shown to be useful in the field for the approximate quantitation of those analytes, thus allowing a substantiated selection of samples for further investigations.

5.2 High-pressure Liquid Chromatography

HPLC is often the separation method of choice for the analysis of NACs. This applies especially for environmental analysis, since in many cases partly reduced metabolites, some of which are not amenable to GC analysis, have to be determined at the same time. Organic acids such as nitrotoluenesulfonic acids or nitrobenzoic acids also cannot be separated by GC without prior derivatization, and are mainly analyzed by HPLC. Another advantage of HPLC is the easier on-line coupling, with an enrichment step in comparison to GC, thus facilitating the set-up of totally automated analysis systems. A disadvantage of HPLC is the incompatibility of common solvents used in LLE with aqueous eluents in reversed-phase HPLC. In these cases a blow-down of the extractant and reconstitution in a suitable solvent is necessary, which might lead to the loss of more volatile analytes. Recent reviews were published on the HPLC analysis of explosives and nitro-PAHs.

Separation of NACs is usually performed with reversed phases and aqueous eluents. Methanol is the most widely used organic modifier, followed by acetonitrile. Depending on the analytes to be separated, isocratic elution may suffice or a gradient elution may be necessary. Some authors describe the isocratic elution with a ternary eluent, although this is seldom used in routine analysis. C18 and C8 stationary phases are mainly used. USEPA method 8030 demands the use of a CN column for confirmatory analysis since the elution order is completely different in comparison with the C18 primary column. The separation method used in the authors’ laboratory is described here in more detail. It is superior to many of the published methods in terms of isomer separation and allows the analysis of at least 16 NACs in one chromatographic run. A typical chromatogram of a reference mixture is shown in Figure 4. For the separation a Nucleosil 120 3-C18, 250 × 3 mm column (Macherey-Nagel, Dueren, Germany) was used with the following gradient: methanol–water 35/65 (v/v), in 12 min to 45% water, isocratic for 28 min, in 10 min to 0% water (for column flushing), then re-equilibration for 15 min with the starting eluent. Flow was 0.35 mL min⁻¹, and detection was done with a DAD.

A selective analysis of NACs is possible with the use of electron donor–acceptor complexes (EDA complexes) formation, which allows separation according to the electron deficiency of the aromatic system. The stationary phase consists of clay conglomerates or silica-based materials which are derivatized to yield electron-rich aromatic systems as end groups (naphthalene, N-methyl indole, anisole).

The separation of neutral and acidic NACs in one chromatographic run was described by Caton and Griest with a mixed-mode C18 anion exchanger column. A similar result can be achieved using acidified eluents or ion-pairing chromatography, since the retention of neutral NACs is hardly affected by pH or the presence of an ion-pairing reagent.

If more powerful separations are needed, the use of two-dimensional chromatography may drastically increase the peak capacity and separation power of the chromatographic system. To maximize these parameters the use of an orthogonal separation mechanism is ideal. Examples in the analysis of NACs are the selective analysis of nitro-PAHs in diesel exhaust particulates and the analysis of water samples for nitroaromatic explosives. In the latter case a safrol-modified silica provided the necessary selectivity difference from the primary C18 column.

A short overview of the most important HPLC detectors for NAC analysis is given in Table 6.

All NACs exhibit the more or less shifted benzene UV absorption bands. Therefore, a UV detector can be generally used, and is indeed by far the most widely applied detector. Instead of using a confirmatory column, nowadays the use of a DAD is generally accepted, which allows compound verification via the on-line measurement of the compound’s UV spectrum. The sensitivity of photometric detection is not very good,

API, atmospheric pressure ionization; NMR, nuclear magnetic resonance.

therefore an enrichment step is always necessary for trace analysis.

Direct fluorescence detection of NACs is not possible because fluorescence is effectively quenched by the nitro group. To utilize such a detector therefore requires reduction to the corresponding amino compounds, some of which show intense native fluorescence (especially the amino-PAHs), but which can also easily be converted with standard derivatization reagents, e.g. fluorescamine, to yield highly fluorescing pyrrolinones.\(^75\) The reduction can either be accomplished pre-column (mainly off-line) or post-column (mainly on-line) with a variety of reductants, including iron,\(^75\) zinc\(^76\) and hydrosulfide.\(^77\)

A disadvantage of the pre-column approach is the more demanding separation of the corresponding amines in comparison with NACs, which mainly result from interactions with residual silanol groups. An especially interesting approach for post-column reduction of nitro-PAHs was recently described by Murayama and Dasgupta,\(^78\) who used a coulometric detector for on-line reduction before subsequent fluorescent detection. By switching the coulometric detector on and off and subtracting both chromatograms they achieved an extraordinary selectivity. Another means to increase selectivity is a post-column reaction scheme which allows chemiluminescence detection.\(^76,77\)

Electrochemical detection of NACs can principally be used in the reductive mode to yield the corresponding hydroxylamines or anilines (see section 4.2). In the review by Lloyd\(^66\) on HPLC of explosives, different techniques for the reductive determination are thoroughly discussed, including hanging mercury drop electrodes and thin-layer electrodes. Cvacka et al.\(^67\) give some examples of the use of amperometric detection in the reductive mode (potential in the range –500 to –650 mV) for environmental analysis of nitro-PAHs. However, a severe drawback of these methods is the interfering oxygen reduction, which leads to high background currents. Therefore a rigorous degassing of eluent and sample and the sole use of stainless-steel tubing is necessary. Still, in many routine applications oxygen interference cannot be avoided sufficiently. Thus the use of electrochemical detection in environmental analysis is more popular for NACs possessing other, oxidizable groups, such as aminonitro compounds or nitrophenols\(^79,80\) which allow operation in the oxidative mode. The electrochemical detector shows a better selectivity (and often sensitivity) than a single-wavelength UV detector. However, use of an electrochemical detector requires much more operational efforts than does a UV detector. Besides, there are still problems with baseline stability in gradient elution, although the developments of the last few years are promising in that regard. An interesting approach was described by Krull and LaCourse,\(^81\) who used a post-column photochemical reactor to cleave nitrite from the analytes, which was then detected in the oxidative mode.

In the past few years, high-performance liquid chromatography/mass spectrometry (HPLC/MS) has gained much attention for NAC analysis, as probably in all fields of HPLC analysis. The MS detection, particularly MS\(^n\), allows in many cases unequivocal identification of analytes, even in difficult matrixes. Many commercialized interfaces have been used for the environmental analysis of NACs: thermospray,\(^82,83\) particle beam,\(^84\) electrospray ionization (ESI),\(^82,83\) and atmospheric pressure chemical ionization (APCI).\(^82\) From the authors’ experience it is expected that ESI and APCI will become the standard interfaces over the next few years. NACs are mostly detected in the negative ion mode since the formation of radical anions
is favored by the electron-withdrawing nitro group. The sensitivity increases with the number of nitro groups and also for organic anions. Astratov et al.\textsuperscript{82} compared the mass spectra of 26 NACs obtained with a thermospray, an APCI and an ESI interface, all operated in negative ion mode with methanol, water and formic acid as the mobile phase. In general, they observed the $M^-$ or $[M - H]$ peak as the base peak with all interfaces. In a few cases, however, the use of APCI and ESI yielded clusters with methanol or formate as the base peak. The fragmentation increased from ESI over APCI to thermospray, reflecting the different thermal stresses prior to or during ionization. Astratov et al. emphasized that there is still a lot of variation in the mass spectra obtained, depending on the use of a specific instrument or interface. They did not provide data on the applied cone (also called fragmentation or capillary exit) voltage. The choice of the cone voltage is crucial for the fragmentation behavior of all NACs but in particular for acidic compounds such as nitrobenzoic acids and nitrotoluenesulfonic acids,\textsuperscript{71} regardless of the interface type. With increasing cone voltage a higher degree of fragmentation is observed. The same behavior was found for polycarboxylates\textsuperscript{80} and aromatic sulfonates.\textsuperscript{87} Thus the cone voltage always has to be set at the same value to obtain reproducible mass spectra. On the other hand the possibility of in-source induced fragmentation offers the possibility of enhanced identification power even in single-quadrupole systems which are not capable of MS\textsuperscript{9} experiments. The ionization behavior of NACs (and other organic chemicals) in modern liquid chromatography coupled interfaces is not at all understood yet and requires a lot of further work.

Another hyphenated method which is increasingly being investigated is high-performance liquid chromatography/nuclear magnetic resonance (HPLC/NMR). Regarding the use for NACs, Preiss et al. did a number of initiative studies, mainly applied to the analysis of contaminated groundwater at ammunition waste sites.\textsuperscript{88,89} This method is unique in its power to reveal the chemical structure of compounds, as even the distinction of positional isomers is possible. Therefore it is well suited for the most complex problems of structural analysis. However, despite advances in the last years, its lack of sensitivity is a major drawback in environmental analysis. Besides, it is very costly both in acquisition and operation and needs an experienced supervisor. Thus it is not expected to become a routine method in the analysis of NACs.

### 5.3 Capillary Electrophoresis and Related Techniques

During the last few years capillary electrophoresis (CE) has gained more and more importance in environmental analysis.\textsuperscript{90} Among the capillary electroseparative techniques, CE, capillary electrochromatography (CEC) and especially micellar electrokinetic chromatography (MEKC) are of interest for the analysis of NACs. Instrumentation for these methods is similar: the main component is a fused silica capillary of a length between 20 and 100 cm and an internal diameter smaller than 100 µm. The capillary, which is filled with the separation electrolyte, is immersed at both ends into vials also filled with electrolyte. After the sample is injected in the capillary, a high voltage (up to 35 kV) is applied between two electrodes immersed into the vials. The temperature of the capillary has to be controlled and the hydrodynamic flow has to be minimized. Detection is usually carried out directly on a segment of the capillary (mostly by photometric or fluorimetric detection).

Whereas in CE only charged solutes can be analyzed because its separation principle is based on different electrophoretic mobilities of analytes, both CEC and MEKC make use of the distribution between two phases, enabling the separation of electrically neutral analytes.

CEC can be regarded as a hybrid technique between HPLC and CE. Using electro-osmotic flow, a mobile phase is driven through a stationary phase which is packed in the capillary. Bailey and Yan\textsuperscript{91} used CEC to separate a series of 14 nitroaromatic and nitramine explosive compounds, achieving baseline resolution for all of the compounds in less than 7 min.

In MEKC, anionic surfactant (usually sodium dodecyl sulfate, SDS) is added to a CE solution, forming micelles. The migration velocity of these micelles differs from that of the surrounding aqueous phase. The micelles are able to incorporate solutes and act as a pseudostationary phase. MEKC does not only extend the applicability of CE to neutral solutes, it also offers improvements in the separation of very complex mixtures. This is due to the numerous possibilities that are available for the manipulation of separation selectivity.

In comparison to classical chromatographic methods like GC and HPLC, capillary electroseparative techniques possess some unique advantages. High separation efficiencies (up to 300 000 plates per capillary) can be achieved easily under routine conditions, even for highly polar or thermal unstable substances, which are in general difficult to analyze. Sample volumes are very small, analysis time is short, and consumption of reagents and costs of columns are low. Moreover, minimal sample cleanup is necessary due to the exchange of the separation electrolyte in CE and MEKC after each run. Irreversible sorption of matrix constituents to the stationary phase cannot occur. Direct sample injection is often possible.

The analysis of trinitrotoluene and its transformation products in a variety of matrices has been a popular subject of studies employing MEKC.\textsuperscript{92,93} Mussenbrock and Kleiböhmer\textsuperscript{94} optimized the separation
of 24 compounds of explosives via MEKC in less than 12 min, including all USEPA priority substances. Oehrle\(^{(95)}\) used MEKC to analyze wastewater samples (called “pink water”) from ammunition plants.

One major disadvantage of capillary electroseparative techniques is the relatively low LOD. Although featuring impressive mass sensitivity comparable to average GC systems, CE with its very small injection volumes of only a few nanoliters is usually not sensitive enough for environmental trace analysis when using photometric detection.

To enhance concentration sensitivity, three basic approaches are possible: increasing detection performance; off-line sample preconcentration; and on-line sample concentration.

The optical pathlength for detection can be increased using special detection cells such as z-shaped cells, multi-reflection cells, rectangular cells and bubble cells. The use of these cells may decrease separation efficiency, however.

For the analysis of NACs with their well-defined redox behavior, electrochemical detection can be useful. Hilmi et al.\(^{(96)}\) presented an off-column amperometric cell for the determination of explosives by MEKC. In comparison to photometric detection, a ten-fold improvement of detection limit was achieved for most of the explosives tested in this study. The results were in good agreement with those obtained by the liquid chromatographic method recommended by the USEPA.

Thermal lens detection can also be used as alternative detection technique. Employing MEKC for the separation of nitrophenol pesticides, Seidel et al.\(^{(97)}\) attained 1–2 orders of magnitude lower detection limits with thermal lens detection than with conventional photometric detection. Another promising effort to enhance sensitivity as well as selectivity is coupling of CE with MS.\(^{(98)}\)

Using off-line sample preconcentration, CE can be employed for the analysis of nitroaromatics in water at ppb levels. Most SPE techniques can be transferred to CE. Rodriguez et al.\(^{(99)}\) used cross-linked polystyrene for off-line concentration of nitro- and chlorophenols from water before separation with CE. Kaniansky et al.\(^{(100)}\) used preparative capillary isotachophoresis (ITP) as a sample pretreatment technique for the analysis of nitrophenols. The following capillary zone electrophoresis (CZE) separation resulted in limits of detection of 2–8 ppb.

Furthermore, capillary electroseparative techniques offer the possibility of on-line concentration techniques that are not applicable in HPLC. One of them is sample stacking, which was initially developed for CZE. A large sample volume is injected. Differences in the effective migration mobilities of the solutes, caused by differences in the electric conductivity of bordering zones, result in focusing of the analytes in a narrow zone. This mechanism is also suitable for the on-line concentration of charged solutes in MEKC. With some modifications it can also be used for the concentration of electrically neutral species in MEKC, as the solutes exhibit an effective migration mobility during the stacking process, due to interaction with the pseudostationary phase.

In summary, capillary electroseparative techniques possess a high potential in this field. In some cases, they already offer a real alternative to GC and HPLC.

5.4 Thin-layer Chromatography

The use of TLC for the environmental analysis of NACs offers some significant advantages. Costs are low and analysis time is short, making this method ideal for screening purposes. Thermal degradation of analytes is insignificant. Moreover, TLC often does not require any sample clean-up. When analyzing soil samples in some cases it is necessary to use size-exclusion chromatography (SEC) to remove large amounts of humic acids.\(^{(101)}\)

Due to the relatively poor separation efficiency of TLC, the method is not sufficient for certain identification of analytes. Two-dimensional TLC can improve separation significantly, employing binary as well as ternary mixtures of solvents.\(^{(41,102)}\)

Automated multiple development high-performance TLC with a commercially available instrument was also successfully applied for the analysis of nitroaromatics and other explosives.\(^{(103)}\) The development of the plate was done employing a stepwise gradient (25 steps) of the solvent, leading to a run time of about 4.5 h. Detection was performed with UV scanning. Detection limits ranged from 5 to 20 ng.

TLC employing different stationary phases was also used for the analysis of nitro-PAHs in environmental samples.\(^{(103)}\)

Kessel and Hauck\(^{(104)}\) developed a TLC method for qualitative screening and quantitative analysis of trinitrotoluene and its main degradation products in water samples after enrichment using SPE.

6 OUTLOOK

In general, the trend in environmental analysis of NACs is determined by advances in extraction, separation and detection methods. As an example it is to be expected that SFE and ASE, due to their ease of use, good extraction efficiencies and automatization possibilities, will become routine methods for the investigation of soil and particulate samples for NACs of all kinds. Separation methods will move to miniaturized systems. With the advent of more and more sensitive detectors,
the use of electrophoretic techniques will increase since they allow the most efficient separations of the whole range of NACs, from rather nonpolar compounds like nitro-PAHs (e.g. with CEC) to nitrosubstituted organic acids such as nitrosulfonic acids. The latter are increasingly recognized as pollutants of concern since their polarity allows fast movement in aqueous systems and penetration in drinking water reservoirs. The importance of oxidized metabolites of nitroaromatic explosives is also underestimated so far, which shows that despite numerous studies we still do not have a complete picture of the transformation processes for NACs in soil and water systems. Besides, nitration processes in the atmosphere are still not well understood. Atmospheric chemistry studies are extremely demanding in terms of analytical methods, and it can be expected that nitration will prove to be of more general importance for the formation of NACs than is known today. Regarding detection, the fast developments in MS are especially promising, both in terms of selectivity (enhancing the reliability of data) and sensitivity. For all ionization methods except EI there is still the need for a better understanding of the underlying mechanisms, thus allowing a better interpretation and prediction of mass spectra. The reproducibility of measurements has to be improved, since quantitation power is still limited. NMR methods may complement MS detection for identification of unknowns if they become easier to handle and cheaper to obtain. However, ECD in GC and a DAD in HPLC will remain the workhorses for NAC analysis in routine laboratories, at least for a number of years.

More sophisticated analytical methods allow the detection of lower and lower quantities of NACs, even in complex environmental matrices. But to derive reliable information on environmental systems still requires more efforts in quality assurance of ultra-trace analyses. One way of providing unbiased data is the use of in situ methods, which will become more important, especially for the surveillance of point sources to aqueous systems. They already allow fast measurements with high temporal and spatial resolution without the problems involved with sampling and storage. Nowadays detection limits and stability of the systems are often not satisfying, but it is expected that both will improve over the next few years.

Nuclear magnetic resonance (NMR) technology is based on discoveries made in 1946, which have provided the basis for many applications in chemical identification, characterization, and imaging. The earliest use was for NMR spectroscopic studies of the molecular distribution of hydrogen, the nucleus detected by NMR with the greatest sensitivity. The use of NMR imaging was first explored in early 1970s, using fruit and vegetable specimens which provided good models for engineering. These early experiments clearly demonstrated the potential utility of NMR for nondestructive visualization of the internal components of intact specimens. Nuclei which can be detected and studied by NMR include those with unpaired electrons, such as $^1\text{H}$, $^2\text{H}$, $^{31}\text{P}$, $^{14}\text{N}$, $^{13}\text{N}$, $^{17}\text{O}$, $^{19}\text{F}$, $^{27}\text{Al}$, $^{23}\text{Na}$ and $^{39}\text{K}$. Contemporary NMR units used for either imaging or spectroscopy have three major components: a large magnet, a radiofrequency (rf) coil, and a computer-driven console to control the pulse sequence and collect data. Samples are placed into the center of the magnet, allowing nuclei to become aligned either parallel or antiparallel to the magnetic field while precessing at a defined frequency which is proportional to the magnetic field strength. The nucleus precession is then realigned to a temporary magnetic field which is perpendicular to the primary magnetic field and is induced by the rf coil. Finally the rf coil is turned off, allowing spins to realign with the primary magnetic field and give off energy which is detected as an alternating current in the process. In NMR spectroscopic experiments, the molecular environment of each nucleus induces slight alterations in the magnetic field, which are detected as slight changes in the frequency of precession. This information is used to create spectra showing details of the molecular environment of the nuclei being detected, and information describing the structure of the molecule. With imaging experiments, electromagnetic coils are placed in the bore of the magnet, to create linearly defined alterations in the magnetic field. As with spectroscopic experiments, the specimen is placed in the center of the stationary magnet. Nuclei are realigned by pulses from an rf coil, and the energy given off is detected as an alternating current. With imaging, changes in the frequency of precession provide information describing the spatial location of the specimen within the bore, and allow images of the specimen volume to be acquired without disruption to the specimen. Use of electromagnets which create a linear magnetic field allows the precise position of the specimen and its morphology to be determined. Contrast within the images is determined both by the content of detected nuclei (usually $^1\text{H}$ within water), and by the interactions between nuclei and their surroundings. The advantage of analysis by NMR spectroscopy and imaging is that the samples can be studied without disruption to the specimen. Chemical analysis can even be done in vivo or in an undisturbed setting. Similarly, imaging can be done on live, intact specimens, the only requirement being that they remain immobile for some period of time. The limitation of these techniques is that only specific nuclei can be detected, with most imaging experiments primarily limited to water distribution and binding. Specimens must be sufficiently small to fit within the bore of the stationary magnet. The magnet bore size may range from a few millimeters for some spectroscopic experiments to up 100 cm with some imaging units. Additionally, the technique is relatively insensitive compared with other analytical techniques such as immunoassays or fluorescent assays. Nevertheless, NMR spectroscopy and imaging provide a unique and powerful set of tools for environmental assessment. Applications include examination of humic substances in soil, soil chemistry, chemistry of surface waters, aluminum chemistry in situ, pesticide fate when introduced into the environment, water uptake and translocation by plants, and structural studies of living specimens such as plant roots within a soil volume. New applications are constantly
appearing as magnet technology improves, new pulse sequences are developed, and coil design progresses.

1 INTRODUCTION

1.1 History and Background

NMR technology is based on discoveries made in 1946 by two groups of researchers, headed by Felix Bloch and Edward Purcell respectively. Its earliest use was in NMR spectroscopic studies of the molecular distribution of hydrogen, the nucleus detected by NMR with the greatest sensitivity. Today, similar spectroscopic experiments provide detailed information on molecular structure, and are used extensively in chemical analysis of many types of molecules. Many texts are available describing applications of NMR in determining molecular structure, and are used extensively in chemical analysis of many types of molecules. Many texts are available describing applications of NMR in determining molecular structure.

NMR experiments can be viewed from the classical perspective, where the nuclear magnetism is derived from the spinning of the nucleus. The precessing motion of the nuclear magnetic moment within the externally applied magnetic field (the superconducting magnet) is described by the Larmor equation, a relationship which is fundamental to all NMR experiments. This relationship can be described as shown in Equation (1)

\[ w = \gamma B_0 \]  

where \( w \) is the frequency which with the nucleus can be considered to precess, \( \gamma \) is the gyromagnetic ratio for the nucleus being considered and is unique for each nucleus, and \( B_0 \) is the strength of the magnetic field.

Following placement in the magnet, the rf coil is pulsed in a prescribed manner at the frequency of precession of the nucleus of interest. This frequency is defined by the Larmor equation, and is directly proportional to the field strength. For example, at 2 T, \( ^1\text{H} \) nuclei precess at 85 MHz, while at 7 T the frequency of precession is
300 MHz. The rf pulse creates a magnetic field, designated B₁, which is perpendicular to the static magnetic field created by the superconducting magnet. This causes the net magnetization of the spins to “tip sideways”, with the degree of tipping depending on the strength and duration of the applied rf pulse. When the rf radiation is turned off, the spins realign with the static magnetic field. During realignment, energy is given off, which is detected by the rf coil as an alternating current. These detected signals are then amplified, filtered, and sent to the computer for digitization, recording, and processing. The process of exciting the nuclei by application of an external rf pulse, realignment, and signal collection is repeated many times for acquisition of an image as well as for most spectra.

For NMR spectroscopic experiments, slight variations in the frequency of precession of individual nuclei are created by interactions with the local environment, creating slight localized changes in the magnetic field, for example patterns of binding or paramagnetic interactions. Spectroscopic experiments, therefore, often provide detailed information describing the molecular environment of the nuclei of interest. There is no information regarding spatial localization of the nuclei in traditional NMR spectroscopy.

MRI is similarly based on the Larmor equation. It capitalizes on the frequency of precession being dependent on the specimen position within the magnet bore. Electromagnetic gradients within the bore of the superconducting magnet create linear, defined increases and decreases in the static magnet field, depending on the direction and distance down the bore from the magnetic field center. If we again consider the Larmor equation, the addition of magnetic field gradients gives the relationship shown in Equation (2)

\[ \omega = \gamma (B_0 + rG_z) \]  

wherein \( r \) is the position along the axis of the gradient \( G_z \). At the isocenter, or the center position of the gradients, the magnetic field is equal to \( B_0 \). The gradient strength increases or decreases linearly from the center position.

### 1.1.2 Fundamental Parameters

There are three fundamental additional parameters inherent in NMR studies: spin–lattice relaxation time \( (T_1) \), spin–spin relaxation time \( (T_2) \), and diffusion. In addition, the number of detectable spins plays an important role in the detected signal intensity. Spin–lattice relaxation is a measure of time required for the spin population to return to equilibrium following excitation by the rf pulse. The spin system transfers its energy to its surroundings, termed the lattice, as a result of interactions with other local, fluctuating magnetic fields. The spins gain magnetization in the longitudinal, static orientation, with reorientation defined as an exponential gain. Spin–lattice relaxation time is described by the exponential function in Equation (3)

\[ M_x(t) = M_0 (1 - e^{-t/T_1}) \]  

where \( M_x(t) \) is the magnetization in the x plane at time \( t \) and \( M_0 \) is the initial magnetization. Spin–spin relaxation is an exponential decay process, describing loss of magnetization in the transverse plane B₁ following the rf pulse. Generally, both \( T_1 \) and \( T_2 \) decrease as water becomes more tightly bound to surrounding substrates and less mobile.

Using imaging experiments, early workers demonstrated that plant roots could be visualized in a variety of fields. The presence of paramagnetic ions frequently found in soils such as Fe²⁺, Fe³⁺, Mn²⁺, and Cu²⁺ shortens relaxation times, with the dominant effect being on \( T_1 \) at low concentrations, and increasing in effect on \( T_2 \) with concentration. When there are sufficiently high concentrations, especially of particulate iron, the relaxation times may be shortened to such an extent that either the image becomes distorted or there is a localized loss of signal in the area near the paramagnetic or ferromagnetic ions. Relaxation rates can therefore give information not only on water binding properties, but also provide indirect information about the chemical environment of the molecules of interest. For example, the measured \( T_1 \) for water in sand can range from 565 ms to 1465 ms, although all sand samples contained 25% w/w water and were of about the same particle size. The differences in relaxation time were due primarily to varied iron contents.

In NMR images, contrast between different regions of a volume being imaged, between a root and the surrounding soil for example, depends entirely upon the inherent properties of the specimen and upon the choice of protocol used for image acquisition. Image or spectroscopic acquisition approaches have been developed which enhance differences in \( T_1 \), \( T_2 \), water distribution, diffusion, and/or flow. Most often, it is a combination of these factors which allows the investigator to distinguish specific features of the specimen under study.

### 1.1.3 Resolution

NMR spectroscopic signals from molecules in solution have a characteristic lineshape, determined by the nuclear magnetic properties, resonance frequency, and spin–spin relaxation times. The natural linewidth at half-height \( (v_{1/2}) \) can be described by Equation (4)

\[ \frac{1}{T_2} = \pi \Delta v_{1/2} \]  

In general, signals or linewidths broaden as molecules become increasingly immobilized and \( T_2 \) decreases.
Therefore, spectra of molecules in metabolites and in extracts frequently have narrower linewidths than spectra of molecules in living tissue or in macromolecules (such as polyphosphates in fungal vacuoles or membrane phospholipids). Generally, as lines broaden they become less detectable or appear as broad lines underlying the signal of other molecules. Magnetic field homogeneity is a critical feature in NMR studies as resonance frequency is determined by magnetic field strength. If the magnetic field is not homogeneous in a spectroscopic study, significant line-broadening can occur, reducing the detectability of nuclei of interest and causing overlap of adjacent peaks. Nuclear magnetic imaging experiments also rely on a homogeneous magnetic field created by the static superconducting magnet. Without this static homogeneous magnetic field, magnetic field gradients created by the electromagnets may not provide the defined, linear magnetic field upon which good spatial resolution is dependent.\(^1\)\(^2\)

Resolution in MRI refers to the digital resolution and is calculated by the field of view size divided by the number of pixels used to create the image. For example, an image of an apple might have a field of view of 100 mm, divided by 256 pixels, thus giving a resolution of 0.39 mm, the measurement on each side of each pixel. Images are acquired from three-dimensional (3-D) specimens, creating a two-dimensional (2-D) image from something which has volume. Typically, in a single slice plant imaging experiment, a slice might be 1 mm thick. Therefore, in an MRI experiment, the term voxel is used to denote the 3-D properties of the specimen. In the apple example, therefore, a voxel would have dimensions of 0.39 mm \(\times\) 0.39 mm \(\times\) 1 mm, or a volume of 0.152 mm\(^3\).

Resolution considerations also usually dictate the choice of imaging equipment. Generally large bore scanners, as would be used in clinical applications, provide resolutions of 0.9 mm or more with a slice thickness of several millimeters. While these resolutions are appropriate for large specimens, generally environmentally relevant samples such as fine roots of plants are of a much smaller diameter and would likely not be detected under such imaging conditions. In contrast, if one is interested in the water distribution throughout a large specimen such as a mature taproot, such equipment might be most appropriate.

An additional consideration with respect to resolution is the process of diffusion, whereby nuclei (i.e. water for most imaging experiments) physically move between voxels during the period of image acquisition. This movement causes loss of signal as the water moves from voxel to voxel, changing precessional frequency as it experiences slight changes in magnetic field strength. This sets the theoretical limit of in-plane resolution to about 1 \(\mu\text{m}\), based on diffusion losses in signal detection.\(^7\) With recent developments in rf coils, the practical resolution in certain cases is approaching this theoretical limit, but generally resolution this fine also dictates a need for small specimen sizes.

### 1.2 Limitations

There are several limitations to the use of MRI in the study of environmental samples. These include the following: the subject for study must generally be smaller than 30 cm in diameter (to fit into the bore of a high-resolution imaging magnet); the specimen must be removed from the study site and brought to the lab for study since it must be placed within the magnet bore; and acquisition of a high-resolution spectrum may take several hours. New pulse sequences (the protocols used for acquiring images and spectra) are continually under development for medical applications, and many focus on shortening the time required to complete a study, which may reduce the time limitation. Many of these new pulse sequences show promise for plant, root, and soil studies. Several previously published reviews summarize applications for MRI in the study of plant physiological processes.\(^5\)\(^8\)

One of the primary disadvantages of NMR is the inherent lack of sensitivity, which can be expressed as a signal-to-noise ratio (S/N) between spectral lines and the background signal (in spectroscopic experiments) or between the signal detected in each pixel and the background signal (in imaging experiments). The S/N is dependent on a wide range of factors including:

1. relative sensitivity of the specific nucleus;
2. the volume of the specimen or sample contributing to each signal;
3. magnetic field strength;
4. the design and construction of the rf coil;
5. the number of times each pulse is repeated and data collected;
6. line-width of the detected signal;
7. relaxation times and their relationship to the chosen pulse sequence and data acquisition parameters;
8. concentration of the specific detectable nuclei (i.e. specific isotopes) present in the sample or specimen.\(^2\)

Generally the minimum concentration required for a specific molecule under study to be detected is 0.2 mM, although experiments can be designed for detection of molecules both above and below this concentration.

There is one fundamental difference between NMR spectroscopic and imaging experiments when determining sensitivity. If we consider a specimen with a volume of 5 mL, when a spectroscopic experiment is performed the signal is acquired from the entire 5 mL volume and is used to produce the resultant spectra. In imaging, however,
spatial encoding digitally separates the specimen into many voxels, each of which is probed individually and contributes its own signal. Many 3-D image sets are comprised of 128 “slices”, with each slice arranged in 256 × 256 pixels. The entire volume is thus divided into 838,8608 voxels. In imaging, therefore, the 5 mL volume is divided into 838,8608 voxels, each with a volume of 0.0006 µL, which is many orders of magnitude less than the volume providing the signal in a spectroscopic experiment. As the signal detected is proportional to the number of nuclei, the signal detected from a single voxel is far less than the signal detected without spatial encoding. For this reason, although many other nuclei can be probed with NMR spectroscopy, MRI is generally restricted to nuclei such as ¹H, which are most readily detected and are highly abundant.

1.3 Potential Applications

Based on its versatility and ability to analyze relatively unprocessed samples, there are numerous applications for NMR techniques in environmental analysis. NMR spectroscopy is often used for the chemical analysis of environmental samples, either directly showing the chemical structure of compounds or through isotopic labelling techniques using NMR-detectable nuclei to show changes in the chemical structure of compounds of interest. Materials studied cover a wide range, including lignin from plants, the fate of pesticides in the environment, phosphorus metabolism in plants, carbon chemistry both in vivo and during decomposition in the environment (root decomposition in soil for example), and speciation of aluminum in biological material as well as in solution (surface waters, for example). Field applications have included the construction of a mobile field unit for the measurement of soil moisture (as described in section 2.2), as well as the study of water content and potential in soil samples. Several texts describe the range of NMR spectroscopic applications to environmental analysis.⁹–¹²

NMR imaging provides spatial information but lacks the sensitivity required for chemical analysis for most detectable nuclei. This technique has found wide acceptance as a diagnostic for human health, and use for environmental monitoring has been strengthened by developments within the medical community. Applications include the imaging of soil, providing some of the first views of soil properties and biology in undisturbed samples. MRI provides an alternative technique to the traditional study of soil which depends on destructive sampling (i.e. removal of plants from the soil volume or disruption of a sample soil core). The strength of the technique is in its ability to nondestructively show root and water distribution within a soil column, either within a core of field soil or a potting container. MRI has also proven extremely valuable in the study of intact, living biological specimens, including animal models for toxicological studies, plant structure and anatomy, water transport and distribution through plant roots, stems, and leaves, and rooting architecture and function.

2 ENVIRONMENTAL APPLICATIONS

2.1 Magnetic Resonance Imaging of Soil

The study of plants in soil has historically presented significant challenges to researchers interested in investigating undisturbed or intact systems. The inherently opaque nature of soil makes direct study of roots or of water distribution within soil difficult without using techniques for remote sensing, such as mini-rhizotrons, X-ray diffraction, computed tomography, γ-ray attenuation, or MRI.¹³,¹⁴ The researcher is physically separated from the specimens, such as plant roots or water distributed throughout a volume of soil, and disruption of the soil volume destroys the integrity and geometry of the system. Soil can present many challenges to MRI and spectroscopic experiments, owing to the inherent heterogeneity of soils. Early in MRI research, it was demonstrated that MRI techniques have the potential for nondestructively observing the spatial distribution of water and large roots in soil. In an extensive examination of the MRI properties of soil, plant roots were imaged when potted into 30 different agricultural and 8 artificial soils. Image quality and the ability to detect roots suffered significantly when the ferromagnetic particle content was greater than 4%. The presence of paramagnetic or ferromagnetic ions and particles within a soil volume creates localized alterations of the magnetic field within the soil volume, distorting the signal received and creating significant artifacts in the subsequent image. Below 4%, there was still significant variation in the suitability of a soil as a root imaging substrate.¹⁵ This is especially important if the objective of the experiment is to make quantitative measurements of root volume, root area, water content, water distribution/flow/diffusion within the soil volume, or other similar measurements.

2.1.1 Experimental Design Considerations

There are several choices to be made when selecting an MRI unit, with a range of sizes and magnetic field strengths determining sensitivity and possible image resolution. The units commonly used for medical applications are constructed of a superconducting magnet with a field strength ranging from 0.5T to 3T (1T or tesla = 10,000 gauss). The size, weight, cost, and technical
difficulties increase with magnetic field strength, however, making high-field magnets with bores large enough to image intact biological specimens or human patients generally impractical with current technology.

In contrast, MRI units that are primarily designed for research generally have magnets with a field strength from 2 T to 9 T. The size of the opening in the magnet for specimen position generally decreases with field strength, ranging from 30 cm to less than 1 cm, depending on the magnet design. For small-volume samples in which the highest resolution is desired, a small-bore, high-field magnet is usually most appropriate. If the specimen is large and the highest resolution may not be necessary, for example in the imaging of logs or large soil volumes, larger bore, lower field strength magnets are used.

### 2.1.2 Water Content and Distribution

Owing to its nondestructive and noninvasive attributes, water potential, content, and movement can be determined through NMR imaging and spectroscopic techniques. MRI has been demonstrated to give information on the pore structure and wettability of natural sandstone, providing visualization of wetting heterogeneities.\(^{[16]}\) The \(T_1\) relaxation time of water in natural sandstone was shown to increase significantly with silanization, changing the wettability of the surface from moderately hydrophilic to hydrophobic. Samples were infiltrated with water, then imaged. Subsequently, there have been other studies using MRI techniques to describe water distribution and flow through porous media such as sandstone, providing information describing the complicated flow and diffusion patterns.\(^{[17,18]}\)

Similarly, the binding properties of water by fine sand as reflected by the relationship between relaxation time and water content have been studied. \(T_1\) values increased from 472 ms when containing 5% water (w/w) to 1265 ms at 25% water. The increase in \(T_1\) was linear between 5% and 20% with a slight reduction in slope between 20% and 25%. The water potential was measured as between 0.01 and 0 MPa, indicating lack of tight water binding by the sand grains.\(^{[5,19]}\)

In addition to the study of soil/water interactions and the water content of soil, MRI provides the ability to study plant/soil interactions at a resolution not previously possible. In addition to spin–lattice relaxation time changes with water content, the detected signal intensity of water in sand increased linearly with water content with some pulse sequences complementing study by more traditional techniques such as neutron activation probes or soil moisture blocks. Studies of both the water content and distribution within the soil/sand matrix surrounding roots and visualization of the undisturbed root system can be achieved. The linear relationship between signal intensity from moist sand and water content allows direct measurement of the water content of sand by MRI when a standardized reference tube filled with copper sulfate solution is placed in the image field of view. The development of varied pulse sequences and the ability to control the environmental conditions within the magnet bore provide the possibility for study of patterns of water distribution and binding within sand (and the influence of roots of transpiring plants) as well as the architecture of roots in an undisturbed soil volume.

Experiments have been conducted to measure quantitative uptake of water from sand by plant roots. In these experiments, pine seedlings were planted into fine sand, watered to field capacity, and imaged repeatedly during a period of transpirational water uptake. Plants remained undisturbed within the bore of the magnet and continued to transpire under illumination from a fiber optic lamp placed into the magnet bore. Over time, regions of low detectable signal were observed to form around the roots which were shown to be regions from which water was withdrawn from the sand by the plants. The “dark” regions surrounding the roots were first observed around the top of the taproot and the fine roots. The margins were seen to expand over time, showing expansion of the root-associated water depletion zones as the plants continued to withdraw water from the sand through transpirational uptake.\(^{[5,19,20]}\)

Water uptake by specific roots can be determined by MRI. Specific regions defined as containing pine seedling roots were imaged, and the areas of the water depletion zone surrounding each root were measured. The amount of water extracted from sand was measured by determining the volume of the water depletion zone by tracing the margins visualized in the images and determining the water content of the sand both within and outside the depletion zones. Comparative measures of water extraction for fine roots, woody lateral roots and the taproot of loblolly and red pine seedlings were calculated. It was found that the fine roots were very efficient at water extraction based on root weight and surface area. What was perhaps more surprising, however, was the formation of a water depletion zone surrounding the developing taproots.

In these experiments it is necessary to first calibrate a standard curve for detected signal intensity, and to include a reference material within each field of view. It is useful to include a glass tube filled with a mixture of water and CuSO\(_4\) solution. The signal intensity of the reference tube and of specific regions of sand are measured from the acquired images. The ratio of these two signal intensities is then fitted to a predetermined regression equation, and the water content of the sand can then be estimated.

This method has provided some of the first views of water extraction by plant roots, and clear evidence that
the woody taproot of pines contributes to water uptake. There are some limitations to the method, however. The first is that image acquisition takes approximately 1h, using a multislice technique wherein images of nonadjacent slices can be simultaneously imaged. For very rapidly transpiring plants, however, this may not be sufficient time for acquisition of high-quality images. A second limitation is that acquisition of a true 3-D volumetric image of the entire soil column and root system requires substantially more time – up to several hours in some cases. Again, if the subject of study is rapidly transpiring, the volume of the water depletion zone may change substantially during the period of image acquisition. The strength and power of the technique, however, generally outweighs its limitations in that it provides definitive information showing the volume and location of the water depletion zone, its spatial relationship to the root system in situ, and water extracted by individual identified roots. A single container can also be repeatedly studied, showing changes in water distribution through time.

2.1.3 Root Distribution and Physiology

Another application is in the direct study of root geometry, architecture, growth, and turnover within the soil column. The nondestructive nature of MRI and NMR spectroscopy allows repeated study of a specific root system. When a root becomes nonfunctional with respect to water uptake, it becomes extremely difficult to distinguish it from the surrounding soil matrix, presumably because it has equilibrated in water content and binding with the soil around it. Images with contrasts primarily weighted by differences in $T_1$ show substantial differences with respect to signals detected between roots and water in the surrounding sand. Thus, root elongation, senescence, and replacement can be seen. This allows functional pine roots to be readily distinguished from nonfunctional roots, a critical distinction with regard to plant health, within an undisturbed soil volume (Figures 1 and 2).

The development of MRI protocols for the acquisition of truly 3-D image sets allows digital extraction of the root system from the soil column, without physical disturbance of the root system in soil. The digitally extracted root system can be measured for volume and surface area using software packages such as VoxelView (BioImage, Ames, Iowa). If appropriate markers are placed in the soil column, or are identified on the root system, image sets can even be registered with one another so more subtle changes can be studied by placing one digital root system alongside or within another. A root can be repeatedly imaged at multiple points in time, allowing quantitative analysis of growth, death, and replacement.

![Figure 1](image1.png)

**Figure 1** 3-D image acquired by MRI of a pine seedling root system. The plant was grown in a sand-filled container and watered routinely to field capacity. The image set was acquired with a spin–echo pulse sequence. The image set has been volume rendered to make the sand and water surrounding the root system transparent, allowing the intact root system to be viewed without removal from the container. Both images are of the same seedling: (a) seedling at approximately 6 weeks of age; (b) seedling at approximately 10 weeks of age.
Again, however, one of the present limitations of the technique is the time required for acquisition of a high-quality 3-D image set using the more common image acquisition approaches. A time requirement of 3–7 h is not uncommon for a single 3-D image, depending on the study requirements. As use of the equipment can be extremely costly, and plant study applications are often competing with studies which generate substantial funding (drug trials, for example, or clinical diagnoses from paying clients), this time requirement may become a serious limitation.

2.1.4 Future for Magnetic Resonance Imaging Study of Soil Systems

The technology is constantly changing, with new imaging protocols in development. In clinical research, it is to the diagnostician’s benefit to decrease the time required for a clinical diagnosis so more patients can have access to the machine in a given period of time. These interests have caused the recent development of many new pulse sequences with a substantially shortened time requirement. While many are not applicable to plant root studies because of the S/N reduction (the smaller voxel size in most plant studies dictates less signal detected for each voxel) compared with medical applications, several hold promise for bringing MRI from the realm of casual interest to becoming a true research tool in the study of plant roots and below-ground processes. Unfortunately, the number of plant researchers who have access to such equipment is limited at present, but with time hopefully this will change.

2.2 Field Application of Nuclear Magnetic Resonance Spectroscopy for Soil Study

One unique application of NMR in environmental monitoring is the use of a mobile, low-magnetic-field-strength unit used in forestry and field settings to measure soil moisture. An NMR unit was designed to be pulled at relatively slow speeds behind a tractor, allowing relatively rapid measurement of surface soil water content over large areas. Field tests have been made at ground speeds from 0–17 km h⁻¹, with a correlation to water content measurements made gravimetrically estimated to be $r = 0.98$.²¹

As the emphasis in environmental monitoring expands to the examination of landscape-scale questions, development of methods to acquire environmentally relevant information at these scales becomes increasingly critical. In support of these studies, remote-sensing techniques (aerial photography and satellite imagery) have emerged as critical tools in the examination of environmental issues. Interpretation of these information sets, however, requires careful ground validation and supplemental testing of the land surface. The mobile NMR spectrometer was designed to characterize soil water content over large areas, to calibrate and verify remote sensor output. Accurate ground-truth information to verify interpretation of measurements made through remote sensing is critical to
accurate interpretation of remote sensor output. Water content, therefore, was determined in the field by measuring the strength of the $^1$H NMR signal from water in the soil.

2.2.1 Experimental Design Considerations and Limitations

Construction of a unit designed for soil water measurements in a field setting requires a magnet to generate the static magnetic field required for resonance, an rf coil with tuning capacitor, and electronics to control the pulse sequence and data acquisition and processing. In addition, the unit must be sufficiently rugged to withstand movement across uneven terrain and exposure to the out-of-doors. In this design, an electromagnet rather than a superconducting magnet was used. The magnet and rf coil with tuning capacitor were designed to be mounted on the back of a tractor, with the electronics located in a weatherproof, air-conditioned steel enclosure mounted just behind the tractor cab. The magnet was approximately 60 cm long with a pole separation of 23 cm. It operated at a relatively low field strength of 700 G. The rf coil operated at a frequency of 3.0 MHz. Electrical power was supplied by a generator mounted on the front of the tractor. Electronics included rf pulse generators, amplifiers, signal processors, and the magnet power supply. The electrical requirements for magnet operation are determined by depth of measurement. Approximately 300 W of electrical power is required for a measurement depth of 51 mm, but approximately 500 W is required with the sensor in the flat configuration. The magnet was fabricated from 512 turns of 0.16-mm thick Al ribbon, bonded to a steel core and encased in a nonmagnetic stainless-steel housing for environmental protection.

Special consideration was needed in the design of the magnet and rf coil. In most laboratory applications, the sample is surrounded by the rf coil, and the assembly is placed in the center of a superconducting magnet. In this arrangement, the sample (the soil surface) was external to both the rf coil and the electromagnet. The size and location of the measurement region are determined by the placement and magnitude of the static magnetic field and the rf field. The poles of the electromagnet are positioned ahead of the measurement region, below the rf coil. As the unit moves across the landscape, nuclei become aligned in the static magnetic field prior to reorientation by the rf field pulse. In this arrangement, the time for the nuclei to align with the static magnetic field is determined by the magnet extension in front of the rf coils, and the transport speed.

In addition to the design constraints, the unit must be constructed for the soil to contact or nearly contact the surface of the unit. The sensor unit can be designed with two different configurations, depending on the application. In the flat arrangement, the sensor rides directly on the soil surface. This provides a stationary arrangement, most suited to flat terrain. In the extended configuration, extended magnetic pole pieces can be positioned into two 10-cm deep furrows. The poles can be adjusted to different soil depths, and NMR measurements of soil water content have been shown to be highly correlated with gravimetrically measured soil water contents at 38, 51, and 64 mm below the soil surface.

The unit was field tested by examining the soil water content of three clay samples (montmorillonite, kaolinite, and illite) and sandy loams with varied levels of organic matter. The soil water contents were measured in the laboratory using standard gravimetric techniques (oven drying and weighing), for comparison with NMR determined measurements.

2.2.2 Software Considerations

A spin–echo pulse sequence was used to measure soil water content, with the amplitude of the spin–echo a measure of the water content. In this sequence, spins are initially aligned parallel or antiparallel with the static magnetic field created by the electromagnet. The rf coil is pulsed, causing spins to realign to a 90° orientation relative to the static field. Spins are pulsed a second time, creating a 180° flip of the spins. The rf coil is then turned off, and the spins are allowed to realign with the primary, static field. Use of the second 180° pulse creates the formation of a signal “spin–echo,” detectable by the rf coil. The rf pulse sequence is completed in 40 µs, and it is repeated 10 times per second, making the pulse sequence repetition time 40 ms. Accumulated signals are acquired for 25.6 s, then averaged.

Spin–lattice and spin–spin relaxation times were determined for water in loamy fine sand (400 ms/40 ms and 200 ms/1 ms respectively) and silty clay (200 ms/5 ms and 130 ms/700 ms respectively). Relaxation times are a reflection of the degree of binding and interaction between water and the surrounding matrix, (soil particles in this case). For the signal detected to be proportional to the number of spins in the sample in NMR spectroscopic experiments (water content in soil in this case) the repetition times between rf pulses should be equal to at least four times $T_1$. Under most conditions, this constraint is met, so the detected signal in the array is proportional to the water content in soil with this choice of pulse sequence and application.

It should be noted, however, that both $T_1$ and $T_2$ values decrease with increasing field strength of the stationary magnet. In addition, the relaxation time for water in other soil types must be determined, since the binding potential of soil and the presence of paramagnetic or
ferromagnetic ions in the soil will greatly affect both spin–spin and spin–lattice relaxation times. Therefore, relaxation times should be determined for each apparatus and field application, and appropriate pulse sequence parameters established for water content determinations.

2.3 Aluminum in Surface Waters

Some forms of Al(III) have been demonstrated to exhibit toxic effects in aquatic and terrestrial ecosystems, affecting fish, plants, mammals, and other organisms, making aluminum study in environmental samples extremely important. Development of methods for the detection and measurement of aluminum is crucial to our understanding of Al(III) chemistry and toxicity in natural waters, soil solutions, and environmental samples. Traditional colorimetric assays, by their very nature, alter Al(III) solution chemistry, potentially biasing measurements. Chemical analysis by complex formation gives specific information on the complexed aluminum species, but may not provide information on other Al(III) forms present in the sample. Magnetic resonance spectroscopic techniques have been developed to measure unaltered Al(III) in aqueous solution, whether from soil, surface waters, environmental samples, or extracts, providing an important tool for the study of this complex, environmental toxicant. 

\[ ^{27}\text{Al} \text{NMR} \text{spectroscopy (spin 5/2, 100\% natural abundance)} \] allows study of the chemical characteristics of the sample without alteration of the inherent chemistry. In addition, as with NMR imaging, the analysis is nondestructive, allowing repeated examination of the sample as needs dictate.

2.3.1 Experimental Design Considerations and Limitations

While Al exists as the most abundant element in the Earth’s crust, it usually occurs at dilute levels (in the order of \(10^{-5} - 10^{-6} \text{ M}^{9-12}\)) in areas of environmental interest such as lakes, rivers, streams, biological samples (fish, plants, etc.), and soil extracts. This is at least one order of magnitude below the sensitivity of most commercial NMR probes. In addition, most vendor-supplied NMR probes and sample tubes designed for multinuclear NMR contain appreciable amounts of Al, resulting in high background signals that mask the desired signals from environmental samples.\(^{22}\)

Techniques to circumvent interference from the probe background include:

1. study of solutions with concentrations > \(10^{-3} \text{ M}\);
2. filtering the broad background signal by increasing the preacquisition delay from 150–200 ms to few microseconds;
3. use of a spin–echo pulse sequence to edit out the background; and
4. use of difference spectra to digitally subtract the probe background.

Since samples of biological and environmental relevance generally have levels of Al in solution well below \(10^{-3} \text{ M}\), studies at high concentrations are often impractical. Concentration of samples to improve sensitivity is also likely to alter the solution chemistry of Al, making this a less-than-desirable choice. Filtering and spin–echo methods can sometimes be effective, but fail when the background and resonance-of-interest have similar linewidths, and may potentially decrease the sensitivity of detection. In particular, broad resonance from Al(III) complexes with biologically important ligands (e.g. organic acids, phosphate, and hydroxy ligands) could go undetected. In difference spectroscopy, the low levels of detectable Al in natural samples make subtraction uncertain, resulting in incomplete background subtraction and “baseline roll”.

To address these challenges and to produce a probe for NMR spectroscopy of Al in solution, a novel probe was designed and constructed to reduce probe background and maximize sensitivity for the detection of \(^{27}\text{Al}\) in solution. The successful construction of such probes provides new tools for the study of Al(III) speciation in dilute, natural samples collected from the environment.\(^{23,24}\)

2.3.2 Coil Design for Environmentally Relevant Measurements

A novel probe was designed and constructed for analysis of environmentally relevant concentrations of Al both in solution and in vivo. To minimize the detectable Al background signal from the probe itself, materials for construction were selected based on prior analysis by neutron activation analysis for Al content. Three primary components were constructed:

1. a probe body constructed of polycarbonate replacing the aluminum components of the housing in commercial probes;
2. a solenoid rf coil designed for increased sensitivity to \(^{27}\text{Al}\) from the sample, tuned by inductive coupling of three separate copper rings rather than by a variable capacitor (which are usually constructed of either ceramic or sapphire, both of which contain detectable aluminum); and
3. a sample holder specifically milled from Teflon\(^{\circ}\) to fit into the rf coil support.

Two separate chambers were constructed, one for a reference solution (\(8 \times 10^{-4} \text{ M Al(OH)}_4, \text{pH} 13\)) and
one for the sample material, either in solution or as biological material. The magnet was a 7-T 89-mm wide-bore vertical magnet. The solenoid coil was assembled around a 3.6-cm-o.d. cylindrical Teflon® insert.

To construct the coil, a 3-cm \times 11\text{-}cm sheet of 2-mil (50-\mu\text{m}) thick microwave substrate was etched to remove about two-thirds of the copper from one side of the strip, while leaving all the copper intact on the other side. The strip was soldered to form a coil sliding freely on the coil support. Two additional copper loops, each 1 mm wide, were placed on the coil form on either side of the main coil. One of these was attached to the coaxial cable to serve as an inductively coupled pickup coil. Tuning and matching were accomplished by adjusting the distances between the three coils on the coil support.

To additionally reduce pickup of aluminum signals from the instrument hardware, unshielded coaxial cables were used for connecting electronic components in the NMR probe, as aluminum braid is frequently used as rf shielding. To reduce background detection, the entire NMR probe, as aluminum braid is frequently used as rf shielding. To reduce background detection, the entire probe was wrapped in copper foil.

2.3.3 Pulse Sequence Design

The coil was tuned to 78.199 MHz at 22°C, and operated without lock. The internal reference material was used to normalize the spectrum. Acquisitions generally included a 40-\mu\text{s} pulse, with a 348-ms recycle delay, a 51-\mu\text{s} readout delay, 8192 points, 11764-Hz sweepwidth, and 10-Hz line broadening. The number of transients collected varied between samples, depending on aluminum concentration.\(^{(2)}\)

2.3.4 Sensitivity Enhancement

The study of Al in natural samples, without alteration of the chemistry present at the time of study or sampling, requires sensitivity as well as specificity. NMR spectroscopy under specific conditions can provide the sensitivity needed for these kinds of studies. Several considerations need to be made to enhance detection. The first is that not all Al ligands are readily detectable. As a quadrupolar nucleus, \(^{27}\text{Al}\) has an inherently broader line and shorter \(T_2\) times than dipolar nuclei such as \(^1\text{H}\). The less symmetrical the Al-containing molecule, the broader the line and the less detectable the ligand. This property in itself provides information describing the molecular geometry, but also presents a challenge to detection. Therefore, molecules which are most likely to be detected at environmentally relevant concentrations are those which are symmetrical, such as Al(OH)\(_4^–\) or AlCl\(_3\).

A second consideration is that \(^{27}\text{Al}\) gives a substantially less detectable signal than \(^1\text{H}\) nuclei, a property linked to both the quadrupolar nature of the nucleus as well as the gyromagnetic ratios. Having more sample available for study is an asset, so use of a wide-bore magnet is extremely valuable in the NMR study of \(^{27}\text{Al}\). In previously reported studies, approximately 11 mL of solution was within the sample volume detectable by the solenoid rf coil. Construction of larger diameter sample containers, to be used at higher field strengths (also increasing detectable signal), would improve the detectability of \(^{27}\text{Al}\) as a potential candidate for environmental NMR study.

2.4 Carbon in Soil – Nuclear Magnetic Resonance of Humic Materials

Humic substances are complex mixtures of organic acids found in soil sediments and in natural waters of the geosphere, and are derived mainly from the weathering and decomposition of plants. Humic material includes macromolecules that have ill-defined structures and are lacking in repeating units. This molecular heterogeneity and complexity has left open to debate many fundamental questions about the structural chemistry of humic substances. NMR spectroscopy has provided useful insights that broaden our understanding of the origins of humic substances, their influence in land and water management, and the fate of pollutants and contaminants.

Humic substances have been extracted and/or methylated and studied in deuterated solvents since the earliest continuous-wave \(^1\text{H}\) and \(^{13}\text{C}\) NMR studies of humic materials.\(^{(9)}\) The first good Fourier transform \(^{13}\text{C}\) NMR spectra showing detailed separation of aromatic and aliphatic resonances of dissolved humic and fulvic acids appeared in 1976.\(^{(10)}\) Direct examination of humic substances in the solid state avoids structural changes due to solubilization, and the first solid-state cross-polarization magic angle spinning spectra of humic material appeared in 1980.\(^{(25,27)}\) This is of particular benefit for NMR studies of the insoluble humin fraction. Complete references to early NMR work are found in reviews published in 1983\(^{(28)}\) and in two books published in 1987.\(^{(10,29)}\) Recent reviews have focused on new \(^{15}\text{N}\) and \(^{13}\text{C}\) NMR enrichment techniques to trace the reactivity of humic substances with regard to degradation and interaction with contaminants and pollutants.\(^{(30,31)}\) The International Humic Substances Society has catalogued standard and reference fulvic and humic acids by \(^{13}\text{C}\) and \(^1\text{H}\) NMR spectroscopy.\(^{(32)}\)

Traditionally, humic substances have been separated into humic acids (base-soluble fractions), fulvic acids (fractions soluble under all pH conditions) and humins (insoluble fractions). Precipitation of the humic acid fraction at acid conditions could hydrolyze phosphate esters. Thus, many researchers today prefer to use
for quantitative data improved NMR spectra of humic substances, particularly from protein material. Nitrate showed signals from secondary amides, most likely in soils. The NMR spectra of organic matter in sediments and by comparison much less widely used.

$^{13}$C NMR spectra of humic substances show overlapping signals in four distinct chemical shift ranges: aliphatic carbon signals (0–50 ppm) from alkyl side chains in amino acids, lipids, and plant polymers; O-alkyl carbon signals (50–110 ppm) from plant carbohydrate and degradation products; aromatic carbons (100–160 ppm); and carbonyl carbon signals (170–200 ppm) from carboxylic acid and carboxamide groups. Carbon signals (170–200 ppm) from carboxylic acid and carboxamide groups. (36,37) $^{15}$N NMR of soil humic acids incubated with $^{15}$N-enriched nates with their direct carbon–phosphorus bond. (38,39) $^{1}$H NMR in the liquid state with poorly resolved envelopes in the alkyl (0–2.5 ppm), O-alkyl (3–4 ppm), and aromatic (6–8 ppm) region is by comparison much less widely used. (9,10) $^{31}$P NMR of soils and sediments allow observation of the inorganic phosphate pool ($P_i$) and the organic phosphate pool ($P_o$) such as phosphate esters, pyrophosphates and phosphonates with their direct carbon–phosphorus bond. (30,31) $^{31}$P NMR results, revealing a larger inorganic phosphate pool in grass and arable soils compared with spruce and deciduous forest soils. (44) Solid-state $^{13}$C and $^{15}$N NMR of $^{13}$C- and $^{15}$N-labeled decomposing ryegrass reveals the O-alkyl-C signal (probably from carbohydrates) and the $^{15}$N signal (probably from $^{15}$N-amides) decreased, while the alkyl- and methyl-C content of soil increased over time. (45,46)

2.5 Pesticide Monitoring In Vivo and In Soil

Dissolved geo-organic matter in lakes and rivers can increase the solubility of pesticides, fertilizers, pollutants, and contaminants and threaten the quality of water supplies. Insights into the interactions of these pollutants with humic materials are needed to understand the migration of these pollutants in the water table. Chemical binding of pollutants to humic substances might decrease the risk of further transport. Irreversible binding, e.g. formation of stable chemical adducts, might be a natural detoxification process. Thus, while much early work centered on assessing the stereochemistry of pesticides themselves and some metabolites, (12) current approaches focus on the combination of labeling and NMR strategies to investigate specific molecular interactions. Anderson has reviewed $^1$H and $^{19}$F solution NMR of pesticide intermolecular interactions, (47) discussing solution complexes of the herbicide atrazine, and the pesticide 1,1,1-trichloro-2,2-bis[p-chlorophenyl]-ethane (DDT), DDT interactions with serum albumin and with phospholipid membranes, and fluoroaromatic–humic acid molecular interactions. Bortiatynski et al. (48) have presented $^{13}$C labeling in combination with $T_1$ relaxation time measurements to study the binding of chlorophenols to humic acid. A covalent complex forms in the presence of an oxidoreductive enzyme. Herbert and Bertsch have used $^2$D and $^{19}$F NMR to study the interaction of nonionic organic contaminants with a Lakeland soil. (49)

1 Introduction

Philosophers tell us that when we look back at our life's journey, the events that we viewed as a series of random unconnected acts when we were living them became instead a path that has cohesion and rationality. Such has been the history of ICP-AES for environmental analysis. These authors remember the pre-ICP (inductively coupled plasma) days when to perform multi-element analysis flame atomic absorption spectrometers were relied upon, which required the use of a different hollow cathode lamp and in some cases a different burner head for the analysis of each element. In the ICP-AES approach, the energy to ICP torch is induced by radio frequency (RF) energy through the three-ring, water-cooled load coil surrounding the three concentric quartz tube torches. Plasma is initiated by introducing a highly energetic electron surge by a Tesla discharge or piezoelectric solid-state transducer. The resulting ions and electrons interact with the oscillating magnetic field produced by the load coil, promoting further ionization of argon gas atoms via collisional interactions, thereby creating sustainable plasma rich with $\text{Ar}^0, \text{Ar}^+, \text{and free electrons.}$ The electron temperature in the plasma can reach $8000–10,000 \text{ K.}$ Thus, the ICP facilitates sufficient energy to the aerosolized sample stream to vaporize $(\text{MX}_g \rightarrow \text{M}_g^+ + \text{X}_g)$ and to atomize analyte elements. In the hot zone of the plasma, electrons in analyte atoms are promoted to higher energy levels (excitation), and, at appropriate plasma conditions, some of these atoms are ionized to form ions $(\text{M}^+ (g))$. Located analyte atoms later...
reach the ground state, emitting characteristic energy at appropriate wavelengths. These wavelengths are unique to each analyte atom, and they can be used to identify unknown elements, while intensities of these emission signals are directly related to the concentration of analyte atoms in the test sample. Argon-based ICP is particularly suitable for exciting a variety of metal atoms and thus facilitates simultaneous multielement capability (Figure 1). By means of an appropriate suite of elemental standards, the instrument can be calibrated. By employing the linear calibration functions obtained for each analyte, one can measure the concentration of these elements in the sample.\(^1,2,3\)

Environmental applications were the driving force in the development of ICP instrumentation. In 1975, under contract to the USEPA, Winge et al.\(^4\) of Ames laboratory reported on the development of ICP-AES for the simultaneous determination of trace element pollutants in water. The USEPA established its first official ICP-AES method for wastewater in 1982 as Method 200.7.\(^5\)

In the 1980s, the decade of ICP, the USEPA approved ICP-AES for the following programs: National Pollutant Discharge Elimination System (NPDES); Safe Drinking Water Act (SDWA); Contract Laboratory Program (CLP); and Resource Conservation and Recovery Act (RCRA). An overview of the USEPA-approved methods for ICP/AES can be found in the *Guide to Environmental Analytical Methods*.\(^6\)

This article expands on the USEPA programs listed above, their effect on the growth of ICP-AES for environmental analysis, and recent “front-end” developments of several sample introduction methods for ICP-AES.

## 2 INDUCTIVELY COUPLED PLASMA DESIGNS

ICP-AES gained a strong foothold in environmental laboratories in the 1980s and 1990s due, in part, to the advantages over its predecessor flame atomic absorption spectroscopy listed here:

- multielement analysis capability
- large dynamic linear range
- improved detection limits for refractory elements and enhancement of productivity.

The early ICP-AES designs of the 1980s that were approved for environmental analysis were of two types: simultaneous and sequential spectrometers with radial viewed torches.\(^7\) The use of the radial viewed plasma results in a shortened path length, which puts the detection limit above the detection limits required by USEPA for elements such as arsenic, lead, selenium, and thallium. For these elements, the USEPA usually required the use of a heated graphite atomizer (HGA).\(^8\)

Later, ICP-AES designs of the 1990s approved for environmental analyses were axial viewed simultaneous and sequential spectrometers.\(^9\) The use of the axial view of the plasma results in a longer path length that greatly improved detection limits and nearly eliminated the need for the use of the HGA to meet the USEPA-detection requirements.\(^10\) With the advent of inductively coupled plasma mass spectrometry (ICP-MS) and by taking the benefit of its high sensitivity and low elemental detection limits, Method 200.8 was first introduced by USEPA in 1990 for the analysis of water.\(^11\)

Recent commercial ICP-AES instruments are not bulky and do not require expensive laboratory space to house them; and they are often bench top versions. In addition, the hardware is more robust, the instrument operational software is user friendly, and the unit price of decent ICP-AES instruments are now more affordable for commercial and research laboratories. During the past 10 years, the major analytical advances in ICP-AES analytical technology have been somewhat slow except for the introduction of solid-state charge transfer detectors and the use of microsample introduction systems including micronebulizer. Solid-state charge transfer detectors (CID) such as charged-coupled devices (CCDs) and charged-injection devices (CIDs) are common nowadays in commercial instruments. These detectors offer simultaneous multielement capability and have lowered the detection limits obtained by ICP-AES, but further work should be done to minimize the analytical limits imposed by the analytical response at the UV range and issues related to the dynamic range and limited pixilation.\(^12\) These solid-state charge transfer

---

**Figure 1** Block diagram for inductively coupled plasma atomic emission spectroscopy (ICP-AES) system.
detectors (CTD) were developed in parallel with the recent development in ICP-mass spectrometry (MS)\(^\text{2,13}\) and reviewed by Mermet.\(^\text{13}\) Plasma robustness can be evaluated by measuring the signal intensity of Mg(I) (at 285.213 nm) and Mg(II) (at 280.270 nm).\(^\text{14}\) Finally, ICP-AES spectrometers that could be programmed for both radial and axial view became the state of the art where the less sensitive radial view was preferred for the higher concentration elements such as aluminum, calcium, iron, magnesium, potassium, and sodium in environmental samples, while the more sensitive axial view was preferred for the lower concentration elements such as the transition series.\(^\text{15}\)

### 3 FRONT-END IMPROVEMENTS IN ICP-AES

The efficient introduction of liquids that offer maximum analytical information is always a challenge for popular pneumatic nebulizer-based ICP-AES techniques. As a result, a series of so-called front-end improvements have taken place during the past two decades (see Figure 1). Some of these improvements were developed in parallel with similar developments in ICP-MS, and some were borrowed from well-established atomic absorption spectrophotometry (AAS). These alternatives include the improvement of nebulizers that can deliver liquids efficiently, introduction of analytes as a gas-phase (i.e., hydride generation (HG) and electrothermal vapor introduction) that will eliminate the introduction of difficult sample matrices, flow injection analysis (FIA) that can introduce small sample volumes that increase the analytical throughput via online analysis, and the separation of elemental species (i.e., As(III) and As(V)) before introduction to the ICP discharge. The former approach has led to the new and exciting field of chemical speciation that offered vital analytical information of environmental and clinical interest. For example, As(III) is more toxic than As(V),\(^\text{16}\) and the ratio of these species’ presence in a given environmental medium is of great importance for an environmental chemist. Resolution of these chemical species requires powerful separation techniques, for example, high performance liquid chromatography (HPLC), gas chromatography (GC), capillary electrophoresis (CE), or size-based separation methods like field-flow fractionation (FFF). These chromatographic or separation methods offer unique chemical and physical separation capabilities before introduction of the separated chemical species to the ICP-based elemental detector. The analytical developments in the chemical speciation area have been noteworthy with ICP-AES, and these advances are extended particularly with ICP-MS. This is partly because the mass spectrometer (MS) is a more sensitive detector than the optical emission detector (OES or aka AES). Some of these so-called front-end improvements are discussed and critiqued at length in the recent literature by Linge,\(^\text{12}\) Mermet,\(^\text{13}\) Becker,\(^\text{17}\) Hansen, and Miró.\(^\text{18}\)

#### 3.1 Solution Introduction via Nebulizer

Although the customary method of sample introduction is a pneumatic nebulizer (~1 mL min\(^{-1}\)) that converts the sample liquid into appropriate-sized aerosol droplets that can be introduced into the plasma source for excitation, this approach has been limited by poor sample-/analyte-transport efficiency.\(^\text{17}\) The alternative to this technique is to introduce small sample volumes using a microflow nebulizer, and a spray-chamber configuration that provides improved sample transport to the plasma and reduced sample consumption.\(^\text{2,17,19}\) A direct-injection, high-efficiency nebulizer, which is widely known as \textit{DIHEN}, can reduce the sample consumption rate down to 30\(\mu\)L min\(^{-1}\), and it was successfully applied to minimize sample matrix effects in both axially and radially viewed ICP-AES.\(^\text{20}\) An attempt has been also made to incorporate a sample introduction system to the ICP excitation source using a microflow nebulizer that is easily snapped to the base of the ICP torch assembly. This torch-integrated sample introduction configuration (\textit{aka TISIS}) has minimized memory effects, and it has been found that matrix effects and nonspectroscopic interferences are minimal.\(^\text{21}\) The elemental sensitivity of ICP-AES and MS had enhanced two to five times by the use of ultrasonic nebulizer (USN), in which the sample is nebulized with the aid of a piezoelectric transducer driven by a high frequency generator.\(^\text{22}\) Clearly, these advancements are a welcome addition to atomic spectroscopists and can be advantageous in analytical applications where the sample size is limited and improved detection limits are needed. These devices are now available commercially through several manufactures that specialize in front-end ICP spectrometry accessories.

#### 3.2 Hydride Generation (HG)

The premise of the HG method is to produce a gas-phase elemental hydride by a reduction reaction,\(^\text{22}\) and to introduce the resulting gaseous hydride (MH\(_n\)) directly to the atom excitation/ionization source (i.e., ICP, flame, and furnace). These reducing reactions are rapid, and are usually achieved by the reaction of the sample with an alkaline solution of sodium tetraborate (NaBH\(_4\)) in an acidic medium (the reducing agent that generates nascent hydrogen). The ensuing hydride (M\(^{x+} + (n + 2)\ H^+ \rightarrow MH_n + H_2\) formed is flushed with a stream of an inert stripping gas like argon. HG reactions
can be achieved on line or by flow-injection modes; therefore, it is convenient for automation. The HG method has been successfully applied for metalloid-based hydrides (AsH₃, SbH₃, and BiH₃) and other elemental hydrides, for example, Ge, Pb, Se, Te, and Sn. More recently, the scope of this approach has extended to transition metals (Zn) and noble metals such as Ru and Rh. The HG method has enhanced analyte-transport efficiency (from 1 to 100%) and has eliminated most of the matrix-based interferences. As a result, the analytical sensitivity of ICP-AES has improved and lower detection limits have been achieved. Furthermore, the sample is introduced as a gas phase, and the input power to the argon plasma is minimized in contrast with liquid-based sample introduction. Selective reduction and subsequent measurement of inorganic arsine species (As(III), As(V)), monomethylarsonic acid (MMA), and dimethylarsinic acid (DMA) using continuous HG mode has been demonstrated with ICP-AES.

3.3 Chemical Speciation with ICP-AES

Although ICP-AES is not the most sensitive detector for elemental speciation, it has been used effectively in several instances where the sensitivity of ICP-AES is sufficient enough to achieve the detection capability of interested chemical species. The element-based chemical speciation field is dominated by ICP-MS as a sensitive detector for many speciation applications. To accomplish chemical speciation, often chromatography-based separation techniques such as HPLC or GC are required. Once separated, the ions (e.g. different oxidation states of Sb(III) and Sb(V)) or metal-bearing chemical species MMA or diethyl mercury – (C₂H₅)₂Hg) can be directly transported into the ICP-AES nebulizer as a sample. The resulting chromatogram (i.e. emission intensity at a selected wavelength vs time) indicates the retention time of the chemical species–associated metals as a peak. The peak area or height can provide quantitative information about these species if an appropriate calibration is made prior to sample analysis. The mobile phase flow rates of HPLC-based separations (1 mL min⁻¹) are suitable for interfacing the chromatograph eluent with the ICP-AES detector, thus providing the capability of automation of metal speciation. HPLC-ICP-AES techniques have been successfully applied for selenoamino acids speciation and the study of cobalt–cysteine interactions, while GC-MS-ICP-AES is reported by Kato et al. (1992) using an axial view of ICP-AES. Size-based separation of metals associated with air particulates in PM₁₀ fractions were determined by flow field-flow fractionation (flow-FFF) coupled with ICP-AES. The authors used sedimentation (Sd) FFF-ICP-AES and applied USN to overcome the poor sensitivity of ICP-AES and small sample mass and dilutions resulting from the Sd-FFF separation process. Later, Saeseaw et al. used FFF-ICP-AES to distinguish Ca²⁺ and Zn²⁺-induced aggregation of β-lactoglobulin aggregates. Application of hyphenated ion chromatography (IC), GC, and CE separation methods to ICP-AES and MS detectors are discussed in the literature.

3.4 Flow Injection Analysis (FIA) in ICP-AES

A small, discrete sample is injected to the flowing carrier solution where the dispersion of the sample into the carrier is controlled by the convection current owing to the carrier stream flow and diffusion owing to the concentration difference between the sample and the carrier stream. The introduced sample can be subjected to on-line reagents to carry out predetermined chemistries, or separation or preconcentration of analytes, to prepare for subsequent detection analytes of interest downstream. In this particular case, the detector is a sensitive multielement detector like ICP-AES or ICP-MS. The resulting FIA curve (or “fiagram”) is a profile of the intensity signal against time. The width of this profile is influenced by dispersion of sample resulting from convection and diffusion forces between the sample and carrier liquids. The recent advancements in FIA analysis are reviewed by Hansen and Miro. FIA has been used effectively to incorporate analysis of hydride-forming elements such as As, Sb, Bi, Se, Te, and Ge for isolation and preconcentration of aluminum species, for on-line standard addition and dilution of trace metals in plant materials, for speciation of Cr(III) and Cr(VI) species, and for on-line multielement analyses of alkaline salts by ICP-AES. The FIA method facilitates rapid throughput of samples and requires a small sample size, therefore it is an attractive method in terms of time and cost of analysis. FIA may suffer from degraded sensitivity. Nevertheless, FIA methods are as good as most traditional analytical methods as far as accuracy and precision are concerned and the selectivity is often better.

4 ENVIRONMENTAL SAMPLE PREPARATION FOR INDUCTIVELY COUPLED PLASMA/ATOMIC EMISSION SPECTROSCOPY ANALYSIS

4.1 Sources of Information

Sample preparation methods for ICP analysis of trace metals can be found in the following sources:

- The USEPA’s Office of Solid Waste prepares and publishes the SW-846 manuals for the analysis of
groundwater, extracts, industrial wastes, soils, sludges, sediments, and solid wastes as dictated by the RCRA.\(^{(39)}\)

- The American Public Health Association, the American Water Works Association, and the Water Environment Federation jointly prepare and publish the *Standard Methods* manual for the analysis of drinking water and wastewater.\(^{(40)}\)
- The USEPA’s Office of Research and Development prepares and publishes its *Methods for the Determination of Metals in Environmental Samples* for the analysis of drinking water, surface water, saline, and industrial and domestic wastes.\(^{(41)}\)
- The USEPA published its *Methods for the Determination of Metals in Environmental Samples* Supplement I that updates sample preparation methods.\(^{(42)}\)
- The USEPA’s Superfund program prepares and publishes its *CLP* manual for the analysis of wastewater and solid waste.\(^{(43)}\)

The following method requirements are taken from the SW-846 manuals to provide the reader with an example of what sample preparation for ICP analysis entails. A compilation of approved methods of ICP sample preparation is presented in Table 1.

### 4.2 Hot Plate Digestions

The acid digestion of waters and solids, employing nitric and hydrochloric acids, can be effected by either hot plate (or hot block) methods or microwave methods. The hot plate methods for the preparation of waters can be quite confusing as they are subcategorized as being either “total” or “total recoverable” – or referred to by some as “hard” and “soft” respectively – where the “total” digestion is more rigorous than the “total recoverable” method. An example of a hot plate “total” digestion

for wastewater is the SW-846 method 3010A and an example of a hot plate “total recoverable” method for ground water, surface water, and wastewater is the SW-846 method 3005A. An example of a hot plate digestion for solids, including sludge and soils, is SW-846 3050B.

4.3 Microwave Digestions

Microwave digestion methods using either closed-vessel or open-vessel microwave digestion systems are approved by the USEPA. Examples of closed-vessel microwave methods for wastewaters and solids are the SW-846 methods 3015A and 3051A respectively. An example of an open-vessel microwave method is SW-846 method 3052, a closed-vessel microwave method, which employs hydrofluoric acid for the preparation of siliceous and organic-based matrices as well as biological tissue, oils, sediment, soil, and sludges, is the only truly “total” digestion approved by the USEPA in which all suspended solids are solubilized.

5 ENVIRONMENTAL INDUCTIVELY COUPLED PLASMA/ATOMIC EMISSION SPECTROSCOPY METHODS OF ANALYSIS

5.1 Sources of Methods

The most used ICP methods of environmental compliant analysis are the USEPA’s Office of Research and Development method 200.7 revision 4.4[44] and the USEPA’s Office of Solid Waste SW-846 method 6010B.[16] Other environmental ICP methods of analysis that are similar to method 6010B include the standard method 3120B,[40] the CLP,[43] and the air force center for engineering and the environment (AFCEE) at http://www.afcee.af.mil/.

The USEPA also approves the use of its method 200.15 for drinking water analysis.[45] This method employs an USN on the front end of an ICP-AES system to provide better detection limits required for drinking water analysis. It is important to note that the USEPA has not yet approved ICP-AES, with or without ultrasonic nebulization, for the analysis of Pb, Sb, Se, and Tl in drinking water. Effective from January 2006, drinking water supply operators have to comply with the new public health goal (PHG) for arsenic in drinking water promulgated by USEPA in 2002. The new maximum contaminant level (MCL) for As in drinking water is 10 µg L⁻¹.[46] This MCL is routinely difficult to achieve by ICP-AES and consequently the EPA has withdrawn the ICP-AES methods 200.7 and the standard method 3120B for the determination of arsenic in drinking water. Now, one has to use either method 200.9 graphite furnaces (GF)-AAS or method 200.8, which is based on ICP-MS.[46]

5.2 Recommended Inductively Coupled Plasma-atomic Emission Spectroscopy Emission Lines

Table 2, taken from method 6010B, documents the suggested ICP emission line of choice and the estimated instrument detection limit (IDL) for radial viewed plasma. Some programs such as the CLP publish contract-required detection limits (CRDLs) that must be met by the instrument of choice (see Table 3). The CRDLs for Pb, Se, and Tl required by the CLP’s Statement of Work (SOW) Inorganic Laboratory Manual Operations (ILMO) 4.0 are 3, 5, and 10 respectively. A radial viewed ICP does not meet these required detection limits. However, an axial viewed ICP meets these

a Detection limit is subject to plasma conditions.
required detection limits and, therefore, has become the instrument of choice for environmental analysis.

5.3 Compensating for Interferences

ICP emission suffers from spectral interferences, and the analyst must document that these interferences have been eliminated. The two most common interferences experienced in environmental ICP analysis are (i) the baseline shift caused mainly by high concentrations of Ca and Mg in samples and due to stray light and (ii) direct spectral overlap due to an emission line from an element in the sample that falls at or near the analyte wavelength and causes a false analyte concentration. Figure 2 shows the effect of both types of interference on the Sb 206.833-nm emission line for an axial view ICP. The calibration standard of 1000-ppb Sb (——) and the calibration blank (----) are superimposed on the graphic that also displays the emission signal for an interference check standard (ICS[A]) with major elements only (- - - -), which contains 500-ppm Al, Ca, and Mg, and 200-ppm Fe as well as the emission signal for a standard that contains 10-ppm Cr, Mn, and V (· · ·).

If left unchecked, the ICS[A] would give a false positive reading of approximately 800-ppb Sb. To prevent this, a background-correction point is programmed slightly to the left of the Sb calibration standard peak (L). During analysis, the emission at the background-correction point wavelength is subtracted from the emission at the 206.833-nm peak wavelength, which effectively reduces the reading of the ICS[A] to less than detectable.

Referring again to Figure 2, the background-correction point does not reduce the reading from the 10-ppm Cr, Mn, V standard since there is a false peak for Sb arising from one of the three elements in this standard (in this case, the interference is due to Cr). To correct for this direct spectral overlap, an inter element correction (IEC) is required and must be documented.

Other interferences normally encountered in environmental ICP analysis are physical or matrix interferences caused by differences in viscosity or the amount of dissolved solids in samples compared to standards. To reduce matrix interferences, analysts are required to prepare all standards and QC samples in the same acid matrix that exists for the digested samples. As a further control, analysts should use an internal standard such as Sc or Y to compensate for physical interferences.

5.4 Quality Control Protocols

After optimizing the instrument according to the manufacturer’s specifications, the analyst is required to analyze a number of QC samples throughout the run where there are decisions to be made on the basis of a window of acceptance for each QC sample analyzed.

The concept of the sample batch is used to describe the number of samples (typically a maximum of 20 samples) that are digested prior to ICP analysis and that are accompanied by QC samples that are also digested. The failure of the digested QC samples (see below) to meet acceptance criteria requires that the samples be redigested.

The complete list of the QC samples as per SW-846 method 6010B is given in the following sections.
5.4.1 Initial Calibration
For SW-846 method 6010B, calibration of the ICP-AES requires one calibration standard within the linear range and one calibration blank. The correlation coefficient of linear calibration curve should be at least 0.995 or better.

5.4.2 Initial Calibration Verification Standard
This standard is prepared from a source different from the source used for the calibration of the ICP. The concentrations of the elements should be at a level that is 50% of the concentrations in the calibration standard. The initial calibration verification (ICV) standard is analyzed after initial calibration of the ICP to verify the calibration curve and must fall within an error of ±10% of the true value. The same analytical wavelength used for calibration of the instrument must be used for sample analyses. Any analyte(s) that fails must be reanalyzed.

5.4.3 Continuing Calibration Verification Standard
This is the same as the ICV but the analysis is after every 10 samples and at the end of the run to monitor the drift. If the continuing calibration verification (CCV) standard falls outside the error window of ±10%, then the 10 samples preceding the failed CCV must be reanalyzed for the failed analyte(s). The concentration of this standard should be closer to the midrange of the calibration curve.

5.4.4 Initial Calibration Blank
This contains the matrix acids and is analyzed after the ICV to monitor contamination and memory effects. If the (initial calibration blank) ICB is greater than three times the IDL, the instrument must be recalibrated for the failed analyte(s).

5.4.5 Continuing Calibration Blank
This is the same as the ICB but the analysis is after each CCV. If the continuing calibration blank (CCB) is greater than three times the IDL, then the 10 previous samples must be reanalyzed for the failed analyte(s). However, if any of the 10 previous samples are greater than 10 times the failed CCB, then these sample(s) do not have to be reanalyzed.

5.4.6 Method Blank
This blank is carried through the entire sample preparation process. Although method 6010B does not provide a definitive QC window, laboratories usually assign the same criteria for the method blank (MB) as for the CCB. In other words, if the MB is greater than three times the IDL, then the samples must be redigested for the failed analyte(s) except for those samples that are more than 10 times the failed MB.

5.4.7 Check Standard
A known standard solution is prepared by an external laboratory.

5.4.8 Interference Check Standard
This standard contains 500-ppm Al, Ca, Mg, 200-ppm Fe, and either 500 or 1000 ppb of all the analytes. The normal nomenclature used for this standard refers to the solution containing the major elements only (Al, Ca, Fe, and Mg) as ICS[A]; the solution containing the 500 or 1000-ppb analytes only as ICS[B]; and the combination of the two solutions as ICS[AB]. The ICS[AB] is used to verify that the background-correction points and the IEC values are programmed correctly. Any analyte(s) that falls outside the error window of ±20% must be reanalyzed.

5.4.9 Matrix Spike/Matrix Spike Duplicate
One duplicate sample is spiked with a known concentration of analytes and is carried through the entire sample preparation process. A separate MS/MSD (matrix spike/matrix spike duplicate) must be prepared for waters, soils, and extracts. The relative percent difference (RPD) of the matrix spike duplicate (MSD) must fall within ±20% error and the spike recovery must be within ±25% error.

5.4.10 Additional Quality Control
In the event that the matrix spike fails to fall within the allowed 75–125% recovery limits, the analyst must perform (i) a dilution test and (ii) a postdigestion spike addition.

1. Dilution test – a 1:5 dilution of the sample is prepared only if the analyte concentration is greater than 10 times the IDL after dilution. The diluted concentration must agree with the undiluted concentration within ±10%.

2. Postdigestion spike addition – a spike containing the analytes at concentration between 10 and 100 times the IDL is added to the digested sample. The spike recovery must be within 75 – 125%.

5.4.10 Preanalysis Quality Control
Prior to any analysis, the following data must be gathered for each ICP-AES emission line:
Table 4  SW-846 method 6010B ICP/AES run log

Organic Acids Analysis in Environmental Samples, Ion Chromatography for Determination of

Sigrid Peldszus
University of Waterloo, Ontario, Canada

1 Introduction

Organic Acids Analysis in Environmental Samples typically focuses on aliphatic short-chain organic acids. The origin of these organic acids and the motivation for their analyses are unique for each type of matrix. Environmental sample matrices are very diverse and can range from air and atmospheric precipitation such as fog, rain or snow to wastewater, drinking water or landfill leachates and soil pore water. This diversity in matrix leads to substantial differences in organic acid concentrations and different organic acid distributions in the various types of environmental samples. Hence, the analytical techniques employed have to be adapted to the particular matrix under investigation.

Ion chromatography is one of the most commonly used techniques for organic acid analysis. Competing ion chromatographic methodologies are anion (ion)-exchange chromatography (IC) and ion exclusion chromatography (ICE). The separation principles underlying each of these techniques are very different and may be used to their advantage. In IC, anions are separated by anion exchange processes between the cationic exchange groups on the resin and the eluent. Hence, inorganic anions and carboxylate anions may be analyzed at the same time (e.g. rain). Limitations of this technique set in when the inorganic anion concentration is much larger than the carboxylate concentration. As a consequence, inorganic anion peaks may mask or co-elute with the analyte of interest. However, techniques have been developed to handle this problem, for example in drinking-water analysis. The separation mechanism in ICE is much more complex than in IC involving Donnan exclusion, adsorption and steric exclusion. ICE is generally used for the separation of weak organic acids since strong organic acids elute in the system peak in the front of the chromatogram. Hence, large concentrations of strong inorganic anions, for example sulfate or chloride, will not interfere with the analysis of weak organic acids. However, organic acids with relatively low pKa values may be difficult to separate from the system peak. In addition, weak inorganic acids such as carbonate have the potential to interfere with the analysis of certain organic acids if present in large enough concentrations.

Other techniques than ion chromatography have been used for organic acid analysis. Direct injections of samples into a gas chromatograph are very common for measuring volatile fatty acids (VFAs) in wastewater. More complex gas chromatography (GC) methods, which include concentration and derivatization steps, have been employed to analyze for specific types of organic acids such as dicarboxylic acids in rain. Capillary electrophoresis (CE) is a newer technique, which has not been used widely in routine analysis. However, speciality applications such as the determination of organic acids in a single raindrop show the potential of this type of methodology.

1 INTRODUCTION

Organic acids are hydrocarbons, which are characterized by their carboxylate function. Their hydrocarbon structure can vary considerably resulting in a wide range of organic acids with different physical and to a certain

a Ohta et al.,1 b Weast,2 c Budavari,3 d Hydroxyacetic acid, e 2-hydroxypropanoic acid, f oxoacetic acid = formylformic acid, g 2-oxopropanoic acid = α-ketopropionic acid = acetylformic acid = pyroracemic acid, h ethanedioic acid, i propanedioic acid = methanedicarboxylic acid, j mesoxalic acids = oxopropanedioic acid = oxomalonic acid, k oxobutanedioic acid = oxosuccinic acid = ketosuccinic acid.

Direct sources of anthropogenic emission include vehicle exhaust fumes and combustion of coal or wood. Directly emitted hydrocarbons can be viewed as indirect anthropogenic sources of organic acids in the atmosphere. These hydrocarbons presumably act as organic precursors, which are oxidized through complex photochemical reactions into organic acids. The ongoing discussion in the literature indicates that it is difficult to elucidate the interactions and the detailed reaction mechanisms of the radicals involved, especially when taking into account the role of the gaseous phase, the water phase and adsorption processes onto particles.

Formic and acetic acid are usually present in much higher concentrations in all of these matrices than any of the other organic acids detected, including dicarboxylic and ketoacids. The total amount of organic acids can be quite significant. It is reported that in North American rain up to one-third of the total free acidity is caused by organic acids. However, it is postulated that organic acids do not contribute significantly to the long-term acidification of the environment since they are easily biodegradable. Research is focusing on gaining more insight into reaction mechanisms as well as cataloging possible emission sources of organic acids.

2 BACKGROUND

2.1 Air and Atmospheric Precipitation

Organic acids in rain were first detected in the 1970s. They also have been found to be present in air and all other forms of wet atmospheric precipitation such as fog, snow and ice. Possible sources of emission are reported to be of anthropogenic as well as biogenic origin. However, little information is available about biogenic sources. Direct sources of anthropogenic emission include vehicle exhaust fumes and combustion of coal or wood. Directly emitted hydrocarbons can be viewed as indirect anthropogenic sources of organic acids in the atmosphere. These hydrocarbons presumably act as organic precursors, which are oxidized through complex photochemical reactions into organic acids. The ongoing discussion in the literature indicates that it is difficult to elucidate the interactions and the detailed reaction mechanisms of the radicals involved, especially when taking into account the role of the gaseous phase, the water phase and adsorption processes onto particles.

Formic and acetic acid are usually present in much higher concentrations in all of these matrices than any of the other organic acids detected, including dicarboxylic and ketoacids. The total amount of organic acids can be quite significant. It is reported that in North American rain up to one-third of the total free acidity is caused by organic acids. However, it is postulated that organic acids do not contribute significantly to the long-term acidification of the environment since they are easily biodegradable. Research is focusing on gaining more insight into reaction mechanisms as well as cataloging possible emission sources of organic acids.

### 2.2 Groundwater

Organic acids can be found close to seeps of naturally occurring hydrocarbons into groundwater, or in the proximity of groundwater sites contaminated with petroleum hydrocarbons. Biodegradation of these hydrocarbons under the anaerobic conditions of the groundwater aquifer leads to a variety of metabolic intermediates, especially organic acids.\(^{(15,16)}\) Although it is expected that the organic acid intermediates are structurally related to the original hydrocarbons, high concentrations of short-chain aliphatic organic acids are most commonly observed, even when aromatic hydrocarbons are the original source. The localized concentration of formate, acetate and isobutyrate combined may be as high as 9000 µmol L⁻¹,\(^{(17)}\) but varies considerably depending on the rate of organic acid production and consumption. Hence, factors such as the proximity to the hydrocarbon source, hydrocarbon loading, presence of microbial inhibitors, availability of nutrients and availability of electron acceptors affect the organic acid concentration in groundwater.

The main effects of high organic acid concentrations in groundwater are mineral dissolution, which leads to changes in soil structure, and complexation of metals such as Fe or Al, which may subsequently be mobilized into the aquifer.\(^{(17)}\) Hence, it is important to take the organic acid production and its consequences into account when observing and projecting the transport of hydrocarbon contamination in groundwater\(^{(17)}\) and when estimating changes in the porosity of oil reservoirs due to organic acid formation in oilfield water.\(^{(18,19)}\)

### 2.3 Drinking Water

Ozone is frequently applied during drinking-water treatment, mainly for disinfection purposes but also to break down taste and odor compounds. Other reasons for its utilization include color removal and pretreatment.\(^{(20)}\) In Europe, ozone has been established in many drinking-water treatment plants for quite some time, whereas in North America, it has only gained interest since the late 1980s. In North America, ozone is often applied with the intention of reducing chlorinated disinfection by-products further by partially substituting chlorine with ozone as the disinfectant.
However, organic compounds which are present naturally, especially in surface water, are oxidized during ozonation, and organic acids and aldehydes are formed as well as a range of other products. Various short-chain aliphatic organic acids (for example formate, acetate and oxalate) have been identified and quantified in partially treated water as a result of the utilization of ozone during drinking-water treatment.\(^{21-26}\)

Concentrations of aliphatic organic acids are highest in the effluent of ozone contactors, where they may reach concentrations of 250 µg L\(^{-1}\) for formate or 195 µg L\(^{-1}\) for acetate.\(^{25}\) Subsequent steps in the drinking-water treatment process reduce these concentrations to low microgram per liter levels or remove them completely.\(^{25}\)

The finished drinking-water is then transported to the customer through a drinking-water distribution system, where any remaining organic acids may contribute to bacterial regrowth, since they are a good nutrient source for microorganisms. Current research conducted in cooperation with the drinking-water industry continues to assess the formation, the removal and the impact of ozonation by-products such as organic acids.

### 2.4 Wastewater

Organic acids are produced in high milligram per liter concentrations during wastewater treatment in anaerobic digesters. These acids are called VFAs and are defined as “water soluble fatty acids which can be distilled at atmospheric pressure”.\(^{27}\) VFAs comprise monocarboxylic aliphatic organic acids with chain lengths of up to seven C-atoms.

Wastewater usually has a high organic carbon (OC) content, which needs to be reduced before the water is discharged into the receiving water body. This is often accomplished by a two-step biological degradation in anaerobic digesters.\(^{28,29}\) First, acidogenic bacteria convert the OC into VFAs with acetate being the major product, followed by metabolism of these VFAs by methanogenic bacteria into methane. These two processes have to be in balance to ensure successful treatment. The difficulty lies in the fact that methanogenic bacteria metabolize at a slower rate than the acidogenic bacteria.\(^{28-30}\) Hence, it is possible that VFAs may not be consumed at the same rate as they are produced, with the consequence that VFA concentrations increase. This in itself may disturb the balance between these processes even further.

Daily monitoring of VFAs is utilized as a sensitive measure of the status of the OC biodegradation. Changes in VFA concentrations indicate disturbances of the biodegradation at an early stage, therefore, making VFA measurement a valuable operational tool in wastewater treatment.\(^{28,29}\)

### 2.5 Landfill Leachates

The anaerobic degradation of organic waste in landfills passes through several stages.\(^{31}\) During the acidogenic phase organic acids, mainly VFAs, are formed in high concentrations and consequently contribute significantly to the OC concentration in landfill leachates. One problem associated with VFA production is the possible mobilization of heavy metals out of the landfill. This is especially of concern when older landfill sites are involved. Older landfill sites often have no liner or only incomplete seals towards the groundwater aquifer and heavy metals may actually be transported into the groundwater.

By monitoring VFA concentrations in landfill leachates, the degradation stage of the landfill itself can be determined. Once VFA concentrations are rising, precautions can be taken to prevent leaking of mobilized heavy metals into the groundwater.

### 3 ION CHROMATOGRAPHY

#### 3.1 Ion Exchange Chromatography Versus Ion Exclusion Chromatography

Ion chromatographic techniques commonly used for the determination of organic acids are IC and ICE which differ significantly in their separation mechanisms.

In IC, separation is primarily accomplished through partitioning of the analyte ions between the mobile phase and the ion-exchange groups bound to the surface of the column resin. Secondary mechanisms may involve adsorption processes. IC columns for the separation of anions are comprised of a copolymer core, usually divinylbenzene crosslinked with polystyrene, to which modified quaternary ammonium groups are bound on the surface. With the development of membrane suppressors, conductivity detectors have found widespread use in IC. They allow for very sensitive detection of ions by suppressing the background conductivity of the mobile phase, which usually consists of hydroxide, borate, bicarbonate or carbonate. Other detectors utilized in IC include amperometric and UV (ultraviolet)-detectors. IC is normally applied to the analysis of strong inorganic anions. However, compounds such as organic acids, which dissociate at the high pH of the mobile phase into ions, may also be analyzed by IC. Depending on the matrix, inorganic anions and carboxylate anions may be determined at the same time, although separation becomes difficult when the concentration of inorganic anions is much higher than...
the concentration of organic acids. This may even result in co-elution and hence masking of organic acid peaks, rendering the particular method unsuitable for organic acid analysis.

Separation in ICE is a much more complex process than in IC and involves Donnan exclusion, adsorption and steric exclusion. ICE columns have high capacities and are usually composed of totally sulfonated divinylbenzene/polystyrene copolymers, which carry strong cation exchange groups. Traditionally UV detection predominates, although conductivity detection is becoming more common. Eluents applied in ICE are aqueous solutions of acids. Dilute mineral acids are mainly in use as eluents in combination with UV detection, whereas strong organic acids such as methanesulfonic or octanesulfonic acid are in use in combination with suppressed conductivity detection. Owing to its specific separation mechanism, ICE is mainly applied to the analysis of weak organic acids in complex matrices. Anions of strong acids, for example sulfate or chloride, elute with the system peak at the front of the chromatogram, thus making this technique suitable for the determination of weak organic acids in samples with high concentrations of strong inorganic anions. Nevertheless, weak inorganic acids, for example carbonate, elute between the organic acids and may, if present in sufficiently high concentrations, interfere with the analysis of the organic acids. In addition, organic acids with relatively low pKa values may be difficult to analyze with ICE, since they elute early, close to the system peak.

More detailed descriptions of theoretical background, instrumentation and applications in IC and ICE can be found in books by Weiss and Haddad and Jackson.

### 4 SAMPLING AND PRESERVATION

Sampling itself is an important part of the overall analytical process. The ideal sampling technique is adapted to the matrix being sampled, prevents contamination and results in an unaltered sample which reflects the average content of the analyte at the time when the sample was taken. To fulfill these criteria different procedures are applied for different types of matrices. A summary of different sampling techniques is given in Table 3.

When dealing with very low concentrations of organic acids, contamination with the almost ubiquitously present organic acids has to be avoided. It was found that organic acids are present on the human skin and wearing gloves is highly advisable in order to minimize contamination from this source.

#### 4.1 Air

Air samples are usually taken by pumping ambient air for a defined time interval, first, through a Teflon® prefiltet to remove particles, and then through a device which retains the organic acids. Devices and processes used for this purpose include filters, scrubbers, denuders, condensation or cryogenic trapping. Solutions used in scrubbers may be water or alkaline solutions. Filters are also impregnated with alkaline solutions and denuders are coated with either NaOH or KOH. Contamination of these sampling devices with the ubiquitous organic acids is easy. Precautions include thorough cleaning of the sampling devices accompanied by regular measurements of blanks. Another problem is the possible formation of artifacts during long sampling periods in the presence of alkali and/or water which makes

DL, detection limit; PAN, peroxyacetylnitrate; HPLC, high-performance liquid chromatography; CZE, capillary zone electrophoresis.
it difficult to distinguish between organic acids trapped from the air and those formed while sampling.\textsuperscript{(34,50)}

Recoveries and DLs in particular vary considerably between these different sampling techniques. DLs can be as low as 10 pptv for formic and acetic acid when utilizing the more established scrubber (recoveries 55–98\%).\textsuperscript{(35,50)} or the relatively new cryogenic trapping technique (recoveries 100\%).\textsuperscript{(50)} When utilizing filters or denuders, DLs are considerably higher (20–450 pptv), though recoveries between 84 and 99\% ensure reliable data.\textsuperscript{(50)}

4.2 Rain

Rain collectors, which are typically set up high above ground, for example on rooftops, consist of a collection container and a funnel. Materials utilized are glass, polyethylene, Teflon\textsuperscript{6} and stainless steel. The design of rain collectors varies from a simple setup like a wide neck bottle with a funnel, which is operated manually, to sophisticated automatic wet-only collection systems.\textsuperscript{4–6,13,14,38–46} The rain collectors must be scrupulously cleaned before each sampling in order to avoid contamination.

Generally, rain collectors are kept shut until the rain event starts so that dry deposition is excluded from sampling.\textsuperscript{(38)} Rainwater is sampled either by rain event or, less frequently, in bulk. When collecting in bulk, rain collectors are replaced after a defined time period. Although this makes operation relatively easy, samples represent only an average of all of the rain events during the past time interval. When sampling by rain event, collectors are exchanged after a single rain event resulting in an average sample of this specific event.

It is also possible to collect individual raindrops, classify them by size and analyze them for organic acids as well as for inorganic cations and anions.\textsuperscript{47,52} This is accomplished with a so-called ‘Guttalgur’. Raindrops entering this collection system during a brief opening period freeze immediately when they come into contact with liquid nitrogen and sink to the bottom of the vessel. The frozen raindrops may then be grouped by size by using sieves with different mesh ranging from 0.1–1.0 mm. The analysis of these individual raindrops with their extremely small volume is accomplished by either CE or micro HPLC.\textsuperscript{47,52}

4.3 Ice

Ice is sampled by drilling cores. These cores are divided into segments which are then analyzed individually. By relating each segment to its date of origin, information can be gained about the composition of the atmosphere in the past.\textsuperscript{(10)} The organic acid concentration in ice from remote areas is usually quite low and care has to be taken to avoid contamination. It was shown that it is not possible to avoid contaminating the outer parts of ice cores considerably with organic acids and ions during the sampling process. These outer layers have to be removed and only the inner parts of the ice core should be used for analysis.\textsuperscript{(48)} Even extended exposure of the melted ice to the laboratory atmosphere may result in contamination with organic acids.\textsuperscript{(48)}

4.4 Groundwater

Groundwater samples are taken from wells by using either a bailer or a pump. To get a representative sample substantial volumes of groundwater have to be removed until pH and conductivity are stable. Only then should the actual sample be taken.\textsuperscript{(16)} Contamination should be avoided by working with clean equipment and storing samples in clean glass containers.

4.5 Drinking Water

Most drinking-water treatment plants have special sampling ports at the different stages of their treatment process. Before taking samples, the lines leading to these ports need to be flushed thoroughly until the water at the sampling port has the same composition as the water at this particular stage of the treatment process. In plants which do not have these sampling ports, bailers have to be used. During sampling, skin contact should be avoided since organic acids are present in significant concentrations on the human skin.\textsuperscript{(53)} Wearing gloves was found to be an appropriate measure to minimize contamination from this source.

4.6 Preservation

Preservation is closely related to the sampling procedure and the measurement technique applied. Ideally it should ensure stable concentrations of the analytes during sample storage while being compatible with the measurement technique utilized later.

The use of IC or ICE techniques requires the sample to be in a liquid aqueous phase prior to injection. If samples are not already in this form, analytes are transferred into the aqueous phase (for example extraction of filters from air samples with deionized water). Samples are usually stored at 4 °C. However, several authors found this to be insufficient to prevent organic acid losses due to biological degradation.\textsuperscript{(13,39,53,55)} As a consequence, preservatives, usually chloroform or mercuric chloride, are added to aqueous samples. When using IC or ICE for sample analysis, adding a small volume of neat chloroform is the preferred preservation technique, since this does not interfere with the measurement.\textsuperscript{(13,39,42,53,55)} In contrast, when using mercuric chloride as a preservative, the mercury cation has to be removed prior to injection (e.g. by
passing the sample through a cation exchanger) in order to prevent poisoning of the IC or ICE column. Hence, mercuric chloride as a preservative is more prevalent in the context of GC measurements. Another, although less common preservative for environmental samples is benzalkonium chloride, which was recently utilized for stabilizing drinking-water samples.

Freezing samples is another option for sample preservation. Ice cores are usually kept frozen and melted just before their measurement. Filters used for sampling air may be stored at −4 °C or −20 °C until they are extracted with deionized water in preparation for their measurement. Sometimes aqueous sample solutions are also stored at subzero temperatures.

5 SAMPLE PREPARATION AND MEASUREMENT

Sample preparation and measurement are intertwined but differ from matrix to matrix. A summary of methods discussed herein, sorted by matrix can be found in Table 4.

5.1 Air

Concentrations of organic acids in air are quite low (very low parts per billion by volume concentrations). They are significantly lower than concentrations of trace gases such as NOx or CO. During the sampling procedure and the subsequent sample preparation organic acids are enriched, resulting in aqueous solutions which contain organic acids in low micromol per liter concentrations.

If alkaline filters or denuders are used as the main trapping device, sample preparation consists in extraction with either deionized water or eluent followed by preservation. If using a scrubber, condensate process or cryogenic trapping as the main sampling technique aqueous solutions are the result and no further sample preparation is required other than immediate preservation. Prefilters, which are used to remove particles prior to air sampling, may be extracted as well. First they are wetted with methanol and then extracted with either deionized water or eluent. The organic acids extracted from these prefilters have been adsorbed onto particles, which were trapped with these prefilters.

All these extracts contain inorganic anions in addition to the organic acids. Fortunately, inorganic anions are present in relatively low concentrations and thus do not interfere with organic acid separation. Organic acid analysis focuses mainly on formate and acetate utilizing both IC and ICE methods, with IC being applied more frequently. Standard columns and conditions are employed as described briefly in Table 4. Additional organic acids such as pyruvate or oxalate may also be analyzed. If utilizing newer columns, which have been developed for the determination of organic acids, an even wider range of organic acids may be analyzed.

5.2 Rain and Snow

Sample preparation for snow samples consists merely of melting, filtration if necessary and preservation. Organic acid content in rain and melted snow range from low to high micrograms per liter concentrations depending on location, precipitation event and type of acid. The more predominant inorganic anions in rain (such as sulfate, sulfite, nitrate and chloride) usually display a somewhat higher concentration. However, in these concentrations they do not cause any major difficulties for the separation of organic acids from inorganic anions. Again, formate and acetate are the major acids of concern and samples may be analyzed by the same standard IC and ICE methods utilized for the analysis of organic acid in air-sample extracts (Table 4). Better yet, some newer IC methods allow for the determination of additional acids such as oxalate as well as for the codetermination of various common inorganic anions (F−, Cl−, NO2−, NO3−, Br−, SO42−, SO32− and PO43−). Hence, these newer IC methods may be preferred over ICE methods, which by nature are only capable of determining weak organic acids.

5.3 Ice

When drilling ice cores it is generally unavoidable to contaminate the outer ice core layers. Hence, these layers have to be removed prior to melting the ice and preserving the resulting solution. Ice from remote areas usually contains very low concentrations of organic acids and inorganic anions (i.e. low nanograms per gram concentrations). In order to measure these low concentrations organic acids have to be enriched. Utilizing a concentrator column online with an analytical column achieves the required low DLs while keeping the sample preparation at a minimum. Concentrator columns suitable for this purpose are small high-capacity anion-exchange columns, which retain the carboxylic anions quantitatively upon loading, if appropriate conditions have been chosen. ICE columns cannot be used as concentrators since water itself acts as an eluent with the consequence that organic acids are not retained quantitatively.

In order to analyze organic acids in ice samples, anion-exchange concentrators have been combined successfully either with an anion-exchange analytical column or with an ICE analytical column. Organic acids determined with these setups are either propionate and butyrate, or

² Columns: Columns are manufactured by Dionex if not mentioned otherwise. AG refers to guard columns, AS refers to analytical columns, ATC-1 is the anion trap column used to purify eluents.

b Detection: Cond. is the conductivity detection, no further details available. Cond. A is the chemical suppressed conductivity detector using H₂SO₄ as regenerant. Cond. B is the suppressed conductivity detection in auto suppression mode. Cond. C is the suppressed conductivity detection in external water mode. Cond. D is the chemical suppressed conductivity detector using tetrabutylammonium hydroxide as regenerant.

c DLs vary with sampling time for air samples.

d Used as concentrator column.
glycolate and oxalate, in addition to formate and acetate. The newer method using the IC/IC combination\(^{(48)}\) achieves lower DLs than the IC/ICE method. Moreover, the IC/IC method has the added advantage over the IC/ICE method\(^{(37)}\) in that inorganic anions (F\(^-\), Cl\(^-\), NO\(_2^-\), NO\(_3^-\), SO\(_4^{2-}\)) can be determined within the same chromatogram as the organic acids.

Concentrator column use is limited by the fact that the analytes have to be retained quantitatively. If anions with strong affinities to the anion-exchange concentrator resin such as inorganic anions are present in higher concentrations, carboxylate anions may be forced off the concentrator column during the loading process, thus leading to irreproducible injections and, hence, irreproducible results. However, inorganic anion concentrations in ice samples are usually low enough so that overloading of the concentrator is very unlikely. Nevertheless, the possibility of column overloading should always be taken into consideration when working with concentrators.

5.4 Groundwater and Soil Pore Water

When dealing with samples from contaminated groundwater sites, organic acid content and matrix can vary significantly depending on factors such as type of contamination, proximity to the contamination and geology. Therefore, organic acid content can fluctuate from low to very high microgram per liter concentrations.\(^{(15,16)}\) Inorganic anion concentrations as well as type and concentration of contaminants also differ widely from site to site. As a consequence, analytical techniques may have to be adapted to the particular sample matrix.

Another aspect of dealing with contaminated groundwater sites is the possible presence of organic solvents and/or metals in these samples. Columns should be compatible with these specific organic solvents, and metals should be removed from the sample prior to injection by passage through H\(^+\) cartridges in order to prevent column poisoning. Nevertheless, filtration is often the only sample preparation step employed in the IC and ICE methods described below.

An ICE method with standard conditions has been successfully applied to organic acid analysis of samples from a groundwater site, which has been contaminated with petroleum hydrocarbons.\(^{(58)}\) Similar ICE methods have been used in the analysis of extracts derived from air samples, and therefore, may also be utilized for groundwater analysis (Table 4). One advantage of ICE methods is the fact that anions derived from strong acids such as mineral acids elute with the system peak at the front of the chromatogram. Hence, inorganic anions such as chloride or sulfate will not interfere with the separation of weak organic acids, even if present in higher concentrations.

Anion-exchange chromatography has been used for organic acid determination in soil pore water\(^{(41)}\) and may also be used for organic acid quantification in a contaminated groundwater matrix, although inorganic anions might interfere with the separation of specific organic acids (for example sulfate/oxalate), especially if they are present at much higher concentrations than the organic acids. Similar problems are encountered during drinking-water analysis, which is why strategies applied in drinking-water analysis may also be utilized for groundwater samples containing high inorganic anion concentrations.

5.5 Drinking Water

Organic acids in drinking-water including partially treated water are only present at low microgram per liter concentrations, if at all. The exceptions are effluents from ozone contactors, an accepted drinking-water treatment practice, where organic acid concentrations may reach medium microgram per liter levels.\(^{22,24–26}\) In contrast to other matrices, concentrations of inorganic anions (Cl\(^-\), SO\(_4^{2-}\), CO\(_3^{2-}\)) in drinking water are much higher compared to organic acids, ranging from low to medium milligram per liter concentrations.

Although different approaches have been taken, it is surprising that no ICE methods for organic acid analysis in drinking water are reported in the current literature. Problems anticipated when using ICE include interferences from weak inorganic acids such as carbonate and separation problems between the early eluting system peak and organic acids with low pKa values such as oxalate or pyruvate.

Anion-exchange chromatography has been used to determine organic acids in drinking water, although very low concentrations of carboxylate anions have to be measured in the presence of large, possibly interfering, inorganic anion concentrations. Slightly different approaches have been taken in the few IC methods dealing with this analytical problem. The focus is usually on formate, acetate and oxalate, although a few other organic acids may be determined as well.

Injection of large sample volumes (for example 760 μL) is one way of ensuring low DLs\(^{(53,55)}\). Owing to the so-called “relaunch effect”\(^{(33)}\) analytes are focused into a relatively small band at the beginning of the column resulting in a chromatogram with narrow peaks, even when injecting larger sample volumes. Subsequent separation is accomplished by a gradient developed specifically for this purpose on a standard anion-exchange column. However, very high concentrations of sulfate can obscure the oxalate peak to the extent that its quantification is impossible. For this type of sample, a two-phase switching technique may be used\(^{(55,59)}\). First, samples
are injected and separated in the manner described previously. At the time window when oxalate is known to elute, the column effluent is redirected onto a concentrator column where the oxalate is trapped. Subsequent reinjection of the concentrator contents onto the same analytical column and application of a different specific gradient makes the quantification of oxalate possible.

In another IC method Hg$^{2+}$ cations, which were initially added to the samples for preservation purposes, have to be removed prior to injection in order to avoid column poisoning. \((24)\) This is accomplished by putting a H$^+$ cartridge, which is exchanged daily, in line just before the injection valve. \((24,26)\) Separation takes place on a specific organic acid column with subsequent suppressed conductivity detection. Utilization of the H$^+$ cartridge is also essential for achieving satisfactory chromatograms, since otherwise organic acids eluting before chloride display broad, plateau-type shapes instead of narrow peaks. Although the injection volume is only 50 µL, sufficiently low DLs are achieved. \((24,26)\)

A different approach is to remove chloride and sulfate before IC measurement through pretreatment with barium and silver cartridges. \((60)\) This should be followed by passing the sample through a H$^+$ cartridge, so that Ag$^+$ cations, which may have leached into the sample from the previous Ag$^+$ cartridge, are trapped thus preventing poisoning of the analytical column with Ag$^+$ cations. A very similar pretreatment procedure is used for low-level bromate analysis in drinking water. \((62,63)\) The treated sample may be injected directly into the ion-exchange chromatograph, where organic acids are separated on a specific organic acid column followed by suppressed conductivity detection. DLs are 20–40 µg L$^{-1}$ for an injection volume of 25 µL.

Using the same approach these limits can be lowered substantially by introducing a concentrator column. \((60)\) The pretreated sample is passed through a strong anion-exchange concentrator column, where the carboxylate anions and other anions are retained. The trapped anions are then eluted from the concentrator onto the separation column in the opposite direction to the loading process. Separation and detection are performed in the same manner as for the direct injection. However, different matrices can contain widely varying concentrations of inorganic anions. Although the majority of the inorganic anions are removed during pretreatment, in the case of very high concentrations this pretreatment may be insufficient. Inorganic anions that remain in the sample may lead to overloading of the concentrator column. Consequently, the less strongly retained carboxylate anions are partially eluted from the concentrator column during sample loading thus leading to irreproducible results. It is therefore important to prevent any breakthrough of the carboxylate anions on the concentrator column when using this method.

### 5.6 Wastewater

Wastewater, especially from anaerobic digesters, displays a high content (milligrams per liter concentrations) of VFAs, which comprise short-chain aliphatic organic acids. The wastewater matrix is quite complex with very high concentrations of organic material and inorganic compounds. \((28,29)\) Landfill leachates have a very similar composition and may therefore be analyzed by similar methods. \((31)\)

VFAs are most often analyzed by GC methods in these matrices. \((30,64,65)\) Only recently has ICE been applied successfully to the analysis of these organic acids in landfill leachate. \((56)\) Samples are usually stored at −18 °C directly after sampling. Sample preparation consists of centrifugation, filtration and removal of humin-like substances by adsorption onto polyvinylpyrrolidinone cartridges. Two different ICE methods have been developed allowing for the determination of organic acids in the samples so prepared. These ICE methods analyze for a wider range of organic acids than the GC methods, hence giving a more complete picture of the organic acid composition in these matrices.

### 6 OTHER COMPLEMENTARY TECHNIQUES

A variety of other techniques beside ion chromatography are used to determine organic acids in various matrices. Only a few methods, which are either of specific interest or very commonly used, will be mentioned.

One of the most frequently used techniques is GC. Determination of VFAs, usually in wastewater but also in other matrices, is often accomplished by direct aqueous injection of samples after minimal sample preparation onto specialty GC columns. \((30,64–66)\) Typically, only VFAs with a chain length from C$_2$ to C$_5$ are analyzed by this method. If the gas chromatograph is maintained properly these direct GC injections deliver fast results, which are utilized as operational parameters in wastewater treatment. Nevertheless, direct GC injection methods are only applicable to samples with high organic acid concentrations (milligrams per liter), since they lack the sensitivity necessary to measure low organic acid concentrations without further extensive sample preparation. In addition, acids such as formic acid or oxalic acid can not be measured by direct GC injection.

Other GC methods focus on the analysis of specific types of organic acid. These methods utilize more
complex sample preparations resulting in methods with high sensitivities and, hence, low DLs. They usually consist of enrichment, derivatization and GC measurement. In fact, even aqueous derivatization may be applied which is the case when determining ketoacids in drinking water. Organic acids determined by this type of GC method include monocarboxylic acids, ketoacids and dicarboxylic acids, often in rain or air matrices.

CE has gained considerable interest in environmental analysis. Advantages of this technique include very fast analysis times, high resolution and the necessity of using only small sample volumes. However, matrix-dependent changes in the migration times of compounds make peak identification difficult even when utilizing internal standards. More detailed information about CE can be found in various books. CZE is the CE technique best suited for the analysis of small ions. One example of applying CZE to the analysis of environmental samples is the quantification of organic acids in single raindrops.

ORGANIC ACIDS ANALYSIS OF ENVIRONMENTAL SAMPLES

Capillary electrophoresis (CE) is an instrumental technique that employs narrow-bore (10–100 µm ID, internal diameter) capillaries under the influence of a high-gradient electric field to perform high-efficiency separations. Different working modes of CE have been described. Capillary zone electrophoresis (CZE) and micellar electrokinetic chromatography (MEKC) have become the most popular modes of CE in environmental applications. Other kinds of electrokinetic chromatography (EKC) and other modes of CE like capillary electrochromatography (CEC) have also been used.

CE techniques have been considered as a good alternative for analyzing pollutants because of their high performance and versatility related to selectivity and range of application. In addition, CE is a powerful tool in the field of chiral separations and it is considered one of the so-called clean analytical techniques. Although the main drawback of CE techniques in environmental analysis is their insufficient sensitivity for detecting trace-level pollutants, some procedures have been developed in order to overcome this problem.

1 INTRODUCTION

Chromatographic techniques are important tools for carrying out analysis of environmental pollutants. Gas chromatography (GC) and high-performance liquid chromatography (HPLC) are the most common techniques used routinely and in complementary form in this type of analysis. Nevertheless, another instrumental technique has been developed as an interesting alternative to HPLC and GC techniques, that is, CE. The utilization of capillary tubes of ID generally ranging from 10 to 100 µm to achieve electrophoretic separations has enabled high efficiencies and an enormous resolution power to be obtained.\(^1\,^{2}\)

Nowadays, the use of CE is one of the major trends in analytical chemistry and the number of publications has increased exponentially.\(^3\) The limitations that GC techniques present for separating nonvolatile compounds (polar, acidic or basic, and thermally labile compounds) and the poor performance that sometimes characterizes HPLC techniques causing loss in resolution and sensitivity, have led to consideration of CE techniques as a good alternative for analyzing pollutants unsuitable for GC and affected by the poor efficiency of HPLC. In fact, they combine the high performance of GC techniques with the versatility of HPLC techniques with respect to selectivity and range of application.\(^4\)

The importance of chirality in environmental control (enantiomers may have a different toxicity or one of them may not be toxic)\(^5\) has given rise to the search for new and effective means of resolving enantiomeric mixtures.\(^6\) The extent to which various chemicals are being applied in agriculture (many pesticides are produced as racemic mixtures and often only one enantiomer is biologically active) will soon require such potential ecological hazards to be monitored enantioselectively\(^7\) and CE can be considered as a powerful separation tool in the field of chiral separations.\(^8\) Aside from all other considerations mentioned here which show the great potential of CE, it can also be considered to be one of the so-called clean analytical techniques. This is due to the small volumes of mobile phase (electrolyte solution) and sample required to perform separations by this technique. This property confers great environmental interest on CE.

Despite the impressive potential for CE to achieve analytical separations, this technique has a major drawback: CE is not sensitive enough to detect trace-level environmental pollutants. Actually, government regulations require determination of lower and lower levels of pollutants in environmental samples so that the concentration
sensitivity of commercial CE instruments is far from ideal. In order to overcome this problem, some procedures to enhance CE sensitivity have been developed and are described below.

2 SEPARATION MODES FOR ENVIRONMENTAL ANALYSIS

Environmental pollutants are organic compounds from ionizable compounds, moderately hydrophobic compounds to highly hydrophobic compounds. Correspondingly, several working modes are needed, and some parameters must be taken into account such as electrolytic solution composition, capillary dimensions, capillary temperature, applied voltage and mode and time of injection. In order to optimize some of the above-mentioned parameters, some mathematical designs have been described. CZE and MEKC have become the most popular modes of CE in environmental applications. Thus, their fundamentals will be described prior to outlining their potential for environmental analyses. Additionally, although less used in the environmental field, other kinds of EKC and other modes of CE like CEC, will be described.

2.1 Capillary Zone Electrophoresis

2.1.1 Fundamentals

The most practical and simple working mode in CE is CZE. Separation by CZE is carried out in a capillary filled with a continuous background electrolyte (buffer). The direction and migration velocity of analytes are determined by two phenomena, electroosmosis and electrophoresis. Electroosmosis originates from ionized silanol groups on the inner wall of the fused-silica capillary which attract positively charged buffer ions to form an electrical double layer. The buffer ions in the mobile region of the double layer will migrate toward the cathode (negative pole) as soon as the voltage has been switched on and induce electroosmotic flow (EOF) of the entire liquid in the capillary. On the other hand, analytes are separated on the basis of their different electrophoretic migration velocities, which are related to their charge densities (mainly based on differences in solute size and charge at a given pH). Generally, the EOF will be higher than the electrophoretic migration velocity of most anionic analytes (which tend to migrate toward the positive pole). Consequently, both cations and anions will migrate in the same direction and can be separated in the same run, eluting initially the positively charged substances, the neutral ones (not separated), and finally the negatively charged solutes. This simplicity has contributed to the popularity of CZE.

CZE can only be used for the separation of ionic or ionizable compounds with low molecular weight and sufficient water solubility. These types of analyte are normally not very amenable to GC requiring, as a minimum, a sample derivatization which presents long sample preparation times and incomplete recoveries for many analyte derivatives. Therefore, the major competition for CZE techniques comes from the HPLC field. However, the higher efficiency of CZE and its different selectivity makes CZE complementary to HPLC. When comparing similar applications, CZE often requires a shorter analysis time and less effort in method development, owing to its huge separation power and flexibility in selectivity tuning. In addition, applications on CZE instruments are much more cost-effective than on HPLC, requiring inexpensive columns and a few milliliters of solutions.

The most important experimental parameter in CZE separations is the pH, except when completely ionized ions are separated. For this reason, some mathematical models have been developed for theoretical prediction of resolution as a function of the pH of the buffer. Other less important parameters are choice of the buffer and its concentration and applied voltage. Unfortunately, many environmental pollutants are related isomers or have very close chemical structures, and therefore CZE often cannot provide sufficient resolution. To improve the separation, CZE has been used with additives such as organic solvents, neutral cyclodextrins (CDs) or neutral polymers. Organic solvents are used as EOF and electrophoretic mobility modifiers to enable the separation of isomers or compounds with closed structures. The use of CDs in CZE has been recognized as a new kind of CZE named cyclodextrin-modified capillary zone electrophoresis (CDCZE). CDs are toroidal, with an axial void–apolar cavity and an outer hydrophilic surface, which form CD-inclusion complexes with certain molecules, based on the concordance of the solute molecular size with the cavity diameter of CD in addition to the hydrophobicity and chemistry. Neutral CDs, despite migrating with the EOF, can form inclusion complexes with molecular compounds which have specific structural arrangements, modifying their electrophoretic mobilities and allowing the separation of pairs of enantiomers or improving multicomponent separation. On the other hand, neutral polymers interact with some analytes decreasing their electrophoretic mobilities and improving the separation.

Recently, cations like cetyltrimethylammonium bromide (CTAB), hexadimetrine bromide (HDB), and other alkylammonium salts have been used to produce a reversal of the EOF and to reduce analysis time of the anionic analytes which migrate in the same direction...
as EOF. This principle is known as coelectroosmotic CE or reversed-polarity CE.\(^{(22–24)}\)

### 2.1.2 Applications to the Analysis of Compounds of Environmental Interest

According to the principles described before, CZE can only be employed to analyze ionic or ionizable pollutants such as pesticides, plant growth regulators, phenols, amines, aromatic sulfonates, alkylsulfates, organometallic compounds and dyes. Table 1 summarizes the analytical conditions used to separate these compounds. These separations have for the most part been monitored by using UV (ultraviolet) absorbance detectors generally used in CE.

Pesticides (e.g. herbicides, fungicides, insecticides) include some compounds that persist in soils or aquatic environments and can be toxic to humans. Ionic and ionizable pesticides can be separated by CZE at the appropriate pH using acetate or phosphate buffers at pH between 3 and 8. In many cases, these compounds have been separated using only a buffer without additives. Examples are paraquat and diquat,\(^{(25)}\) sulfonylureas,\(^{(26)}\)

</table>
phenoxo acids\(^{(27)}\) and alkylphosphonic acids.\(^{(28)}\) In other cases, the CZE buffer contains additives such as organic solvents or CDs. Thus, prometon and prometryne (triazine herbicides) have been separated with a neutral buffer containing acetonitrile.\(^{(29)}\) On the other hand, it is important to note that the addition of CDs to the separation buffer allows enantiomeric separation of several phenoxo acid herbicides.\(^{(27,30,31)}\) Figure 1 shows the chiral separation of three optically active phenoxo acid herbicides in their six enantiomers by CZE using an acid buffer with tri-o-methyl-\(\beta\)-cyclodextrin (TM-\(\beta\)-CD) as additive.\(^{(30)}\) They were separated from another nonchiral phenoxo acid at microgram per milliliter levels in an analysis time close to 12 min.

Plant growth regulators have been easily separated using a basic buffer with a cocktail of \(\alpha\)-, \(\beta\)-, and \(\gamma\)-CDs in order to enhance the selectivity.\(^{(32,33)}\)

Phenols are important environmental pollutants owing to their high toxicity even at low concentrations. They are weak acids which can ionize in aqueous solutions and then can be analyzed easily by CZE using a buffer without additives. The pH chosen for the buffer depends on the types of compound, using phosphate or phosphate/borate buffers for neutral or basic pH values, respectively. Thus, the analysis of several chlorophenols requires a neutral pH,\(^{(34,35)}\) although the eleven priority pollutant phenols listed by the USEPA (including chlorophenols, alklyphenols and nitrophenols)\(^{(34)}\) and eight substituted phenols (different methyl-, dimethyl- and trimethylphenols)\(^{(36)}\) have been separated using basic conditions. The 11 USEPA priority phenols can be completely resolved in less than 15 min by CZE (see Figure 2).\(^{(34)}\) In this case, CZE provided better results than MEKC, because the analysis time was noticeably shorter compared with the 45 min obtained with MEKC,\(^{(47)}\) or the 25 min typically required by HPLC.\(^{(48)}\) Optimum conditions included a small buffer concentration and a basic pH, under which all phenols except one were ionized. Detection was performed with an on-column UV detector and good linealities \((r \geq 0.999)\) were obtained for concentrations up to at least 50 ppm, with detection limits less than 1 ppm. On the other hand, the rapid analysis of substituted phenols has been achieved by using a buffer with a high pH value and HDB with propanol as additives.\(^{(22,23)}\) In this method, the principle of coelectroosmotic CE, described above, was used. The application of CE techniques to the analysis of phenols has been reviewed.\(^{(49)}\)

Amines such as heterocyclic amines are carcinogenic and mutagenic compounds that are found in cooked foods. Others like aromatic amines can contaminate water and soils. Based on their positive charge in acidic solution, several phenylenediamine isomers\(^{(37)}\) and chloroaniline isomers\(^{(38)}\) have been separated by CZE easily using only an acid buffer. On the other hand, the separation of 12 heterocyclic amines was optimized by orthogonal array design and the optimum conditions included the use of an acid buffer with NaCl and methanol as additives.\(^{(11)}\)

Aromatic sulfonates are compounds separated by CZE using only basic buffers.\(^{(39)}\) Alkylbenzene sulfonates are anionic surfactants widely used in detergent formulations, which have been separated by CZE using basic buffers with acetonitrile as additive.\(^{(40)}\) The results show that CZE is more selective than MEKC for these compounds and the resulting analysis time is at least three times shorter compared with HPLC.\(^{(50)}\)

ORGANIC ANALYSIS IN ENVIRONMENTAL SAMPLES BY CAPILLARY ELECTROPHORESIS

10 12
Time (min)

Figure 1 Chiral separation of three optically active phenoxy acid herbicides and another nonchiral phenoxy acid by CDCZE. Conditions: separation media, 0.05 M acetate buffer (pH 4.5) with 0.025 M TM-β-CD; capillary tube, 75 µm ID x 50 cm (to the detector); hydrodynamic injection, 5 s; applied voltage (current), 20 kV (41 µA); UV-detection at 230 nm; temperature, 30°C. Peaks (analyte concentration, 1 µg mL⁻¹): (1) 2-(2,4,5-trichlorophenoxy)propionic acid, (2) 2-(2-methyl-4-chlorophenoxy)propionic acid, (3) 2-(2,4-dichlorophenoxy)propionic acid and (4) 2,4-dichlorophenoxyacetic acid. (Reproduced by permission of Elsevier Science Publishers. Copyright (1994), from A.W. Garrison, P. Schmitt, A. Kettrup, J. Chromatogr. A, 688, 317–327.)

Separation of C₉–C₁₂ sodium alkylsulfates was followed using indirect UV detection because there is no chromophore in the analyte molecules. (41)

Organometallic compounds such as organotin compounds have been analyzed by CZE employing an acid buffer and pyridine (42) or BTMA (43) to enable indirect UV detection. Methylmercury has been separated from an excess of cysteine at basic pH, using different reference materials. (44)

Dyes are colorants employed in the food and textile industries which frequently contaminate the aquatic environment. Some of them are anionic compounds suitable for analysis by CZE. Thus, seven food additive dyestuffs (45) and eleven permitted food colorants (46) have been separated using neutral buffers with CDs. Other synthetic dyes used as colorants for textiles have been separated using a neutral buffer with PEG and PVP as additives. (20) Reactive dyes have also been separated with an acid buffer and acetonitrile as additive. (24)

2.2 Micellar Electrokinetic Chromatography

2.2.1 Fundamentals

Even though CE was initially limited to the separation of charged compounds, the introduction of a micellar system in the separation buffer in 1984 (51) which resulted in the so-called MEKC, enabled CE to be applied to the separation of noncharged compounds. (52–56) In this technique, ionic surfactants are added to the CZE buffer at concentrations exceeding the critical micelle concentration (CMC) to form micelles which act as a pseudostationary phase. (57) The micelles are spherical aggregates whose hydrophobic groups are oriented toward the center of the micelle, with polar or charged groups along the sphere’s surface. In this situation, neutral analytes are distributed between the buffer phase (which migrates with the velocity of the EOF) and the micellar phase (which moves at a velocity slower than EOF), resulting in separation. Because the micellar phase moves toward the detector, an elution window is created that...
is bordered by a column void time \( t_0 \), mobility of the EOF) and a micelle migration time \( t_{MC} \) of the micelle). All the analytes must elute between these two limits, \( t_0 \) and \( t_{MC} \), depending upon their partition between aqueous and micellar phases.\(^{58}\) On the other hand, the migration behavior of ionizable solutes is more complicated because their electroophoretic mobilities have a great influence on the migration behavior and selectivity.\(^{47}\)

Unfortunately, highly hydrophobic compounds tend completely to associate with the micelles and are not resolved because they coelute near \( t_{MC} \). In order to enhance the usefulness of this technique, organic solvents (methanol, acetonitrile, tetrahydrofuran, or acetone),\(^{59-61}\) and urea\(^{62}\) were added to the buffer. In this case, the separation selectivity in MEKC can be controlled through the nature and concentration of the buffer and surfactant in the electrolyte solution and the nature and concentration of organic additives.\(^{63}\) As an alternative to the addition of organic solvents (aggregation numbers and CMCS are affected by the addition of small amounts of organic modifier, and micelles are generally not stable in buffer with a high organic solvent content),\(^{64,65}\) neutral CDs\(^{66-71}\) are extensively used as modifiers in MEKC, giving rise to cyclodextrin micellar electrokinetic chromatography (CDMEKC). In CDMEKC, neutral CDs will not interact with the micelle owing to its hydrophilic outside surface, but a hydrophobic solute is partitioned between the micelle (which migrates with the micellar velocity) and CD (which migrates with the EOF). Accordingly, the differential partition of the solute between CD-monomers and the micelles allows a separation.

The most widely used surfactants in MEKC have been those which are anionic in nature, especially sodium dodecyl sulfate (SDS) alone or with the additives previously described. Other possibilities, such as mixed micelles between SDS and neutral surfactants (Brij 35 [polyoxyethylenelauryl ether])\(^{72}\) or PEG 400 monolaurate\(^{73,74}\) or SDS homologs (sodium tetradecyl\(^{52}\) or decyl\(^{75}\) sulfates) were tested to alter resolution and selectivity, but narrower retention windows or irreproducible times were obtained.

Bile salts, especially sodium cholate (SC) and sodium deoxycholate (SDC), have been considered promising pseudostationary phases in MEKC. They are important biological surfactants, based on a hydroxy-substituted steroid backbone, which form helical micelles with the hydrophobic portions of the monomer facing the aqueous solution while the hydrophilic portions turn inward. Thus, in some respects, bile salt micelles can be envisioned as “inverted micelles”.\(^{76,77}\) Their structure and aggregation behavior allow chiral recognition\(^{78-80}\) and reduction of retention factor values with respect to those obtained with SDS.\(^{81,82}\) In addition, bile salt micelles appear to tolerate high concentrations of organic solvents without drastic loss of efficiency or dramatic increase in analysis time.\(^{65}\) These factors facilitate the analysis of hydrophobic compounds more easily than with SDS.

On the other hand, in situ charged micelles\(^{83-86}\) are essentially anionic complexes formed between alkyl- or steroidal-glycoside surfactants and borate anions. They possess many unique and attractive features:

1. The surface charge density and the elution window increase with an increase in pH (upper 8) or borate concentration (25–400 mM).
2. Owing to the more balanced hydrophilic–lipophilic character than alkyl ionic surfactants, they are useful for separating hydrophobic compounds.
3. Some in situ charged micelles have chiral selectivity.\(^{87}\)

Finally, although employed less in the analysis of environmental pollutants, other compounds have been used as micellar phases in MEKC:

1. different micelles such as alkyltrimethylammonium,\(^{88}\) especially CTAB, disodium 5,12-bis-(dodecyloxyethyl)-4,7,10,13-(tetraosa)-1,16-hexadecanesulfonate (DBTD)\(^{89}\) and butyl acrylate–butyl methacrylate–methacrylic acid copolymers sodium salts (BBMA);\(^{90}\)
2. oligomers with micelle-like structure such as sodium 10-undecyleenate (SUA)\(^{91}\) and sodium 10-undecylsulfate (SUS);\(^{92}\)
3. macromolecules that are considered to mimic micelles such as dendrimers\(^{93-95}\) and resorcoranes.\(^{96}\)

MEKC systems compared with CZE are more complicated because of the additional experimental parameters that must be optimized\(^{97}\) and because their electrolytic solutions are less stable than CZE buffer solutions owing to the effect of temperature on the distribution equilibria involved. In addition, the theoretical plate number in MEKC is not usually as high as could be achieved by CZE owing to the mass transfer resistance introduced by solute partitioning between the two phases. Consequently, sensitivity in MEKC is expected to be lower than in CZE.\(^{98}\) Despite these drawbacks, MEKC has extended the enormous power of CZE to the separation of uncharged solutes and, moreover, it has demonstrated additional selectivity. This offers a good alternative for pollutants that are not amenable to CZE because they are electrically neutral solutes.
2.2.2 Applications to the Analysis of Compounds of Environmental Interest

MEKC is a mode of CE suitable to analyze neutral environmental pollutants such as mycotoxins, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polychlorodibenzo-p-dioxins (PCDDs), or phthalates, and ionizable or ionic contaminants such as pesticides, phenols, dyes, amines, nitroaromatic compounds, organometallic compounds and sulfonates. The experimental conditions used to separate these compounds are grouped in Table 2. MEKC has been performed with several detection systems, such as UV absorbance, LIF, amperometric detection, and MS.

Mycotoxins are produced by fungi and they constitute a common class of environmental pollutants. Conventional methods for mycotoxins analysis are thin-layer chromatography and HPLC; however, these methods are very time-consuming and labor-intensive. These compounds, which cannot be analyzed by CZE, have been successfully resolved using MEKC. Three aflatoxins (mycotoxins that occur in a variety of foodstuffs intended for both livestock and human consumption) were separated by MEKC using SDC as surfactant in about 15 min. The separation of 10 mycotoxins was optimized (fully resolved chromatograms in only 15 min) using two different MEKC systems, SDS with acetonitrile.

and γ-CD, or SDC with acetonitrile. Comparing the retention characteristics of sample and standard components under different MEKC conditions increased the reliability of peak identification.99

The separation of highly hydrophobic compounds and closely related compounds (PAHs, PCBs and PCDDs) is generally difficult by electrophoretic techniques, as explained before. In addition, it is often difficult to dissolve sufficient analyte in the aqueous micellar solution to enable detection by standard on-column UV detection. In an attempt to address these problems, several research groups have experimented with different separation procedures, which have been devoted to the separation of PAHs as shown in Table 2. PAHs which contain
at least two aromatic rings in their basic structure are of great environmental concern owing to their carcinogenicity. Multicomponent separations of PAHs have been carried out by MEKC using basic buffers with different surfactants to form the micellar phase such as SDS, SC, SDC, or CTAB. The addition of organic modifiers to an electrophoretic medium is particularly advantageous for the analysis of hydrophobic analytes because they reduce the analytes’ relative affinity for the micellar phase and increase solubility. CDs (CDMEKC) have been also employed to enhance the separation of highly hydrophobic compounds such as PAHs. The separation of a mixture of 20 PAHs by CDMEKC is illustrated in Figure 3. Finally, other authors have reported the separation of several PAHs using different pseudostationary phases:

1. in situ charged micelles such as MEGA
2. mimetic micelles such as oligomers (SUA and SUS), dendrimers (SBD(X)-C12) or resorcarenes,
3. combined polymerized chiral micelle with CD.

PCBs and PCDDs are persistent environmental pollutants toxic to humans and animals. The separation of these compounds by MEKC is difficult owing to the low selectivity of the system in separating highly hydrophobic compounds. The addition of CDs and urea (increasing the solubility of hydrophobic compounds and CDs in aqueous media) to the separation buffer in MEKC has enabled the separation of PCBs and PCDDs. CDMEKC using SDS with γ-CD and urea in the separation buffer has enabled successful separation of 11 trichlorobiphenyl isomers, three pairs of trichlorodibenzo-p-dioxins, different PCDD isomer pairs and 14 PCB congeners. CTAB has been used as surfactant in CDMEKC to separate 10 PCB congeners. In addition, CDMEKC with SDS has been employed to achieve the enantiomeric separation of 12 chiral PCBs each one in its two enantiomers using γ-CD alone or mixed with β-CD in the buffer. Multicomponent mixtures of nine or eight chiral PCBs were separated. Figure 4 shows the separation of the 18 enantiomers of a mixture of nine chiral PCBs, containing one octachlorinated biphenyl, in an analysis time close to 35 min. Bile salts are alternate micellar systems for the separation of chiral compounds by MEKC and their use to separate three chiral PCBs, each one in its two enantiomers in less than 30 min has been described.
Phthalates are widely used as plasticizers in industry, and can migrate from the plastics into the environment, so they are common contaminants in aquatic environments.\textsuperscript{153} USEPA method 606 specifies analysis by GC with an electron capture detector, but appropriate pretreatment is necessary. The separation of six and ten phthalate esters, including some priority pollutants, was achieved by MEKC using SDS alone\textsuperscript{114} or with methanol as additive\textsuperscript{115} respectively. The use of SUA as a pseudostationary phase, in the presence of relatively high

\textbf{Figure 4} Electropherogram corresponding to the separation of a mixture of nine chiral PCBs by CDMEKC. Conditions: separation media, 0.10 M CHES buffer (pH = 10.0) with 2 M urea, 0.11 M SDS and 0.05 M \(\gamma\)-CD, capillary tube, 50\(\mu\)m ID \(\times\) 65 cm (50 cm to the detector), injection by pressure, 0.02 min at 20 mbar, applied voltage (current), 15 kV (56 \(\mu\)A), UV-detection at 235 nm, temperature, 45 °C. Peaks: DMF, each pair of enantiomers is identified by IUPAC number (according to Ballschmiter nomenclature; K. Ballschmitter, M. Zell, \textit{Fresenius Z. Anal. Chem.}, \textbf{302}, 20–31 (1980)); and (A) unknown peak. (Reproduced by permission of Chromatographia Vieweg-Publishing from M.L. Marina, I. Benito, J.C. Diez-Masa, M.J. Gonzalez, \textit{Chromatographia}, \textbf{42}, 269–272 (1996).)\textsuperscript{111}
amounts of organic modifier (acetonitrile), allows the separation and analysis of hydrophobic analytes such as phthalates.\(^{191}\) The major disadvantage of this new phase lies in its laborious preparation (>2 days).

Pesticides have been widely studied by MEKC as shown in Table 2, since although they can be also separated by CZE, in some cases the separation can be enhanced by MEKC. Thus, multicomponent separation of different types of herbicides such as phenoxy acids, triazines, and phenylureas have been carried out by MEKC using mainly SDS\(^{116 – 121, 144}\) as anionic surfactant and other in situ charged micelles such as MEGA 8, MEGA 9 or MEGA 10.\(^{33, 83 – 86}\) Also, several phenylurea herbicides have been successfully separated using cationic micelles such as TTAC with OTAC or DTAC.\(^{88}\) On the other hand, enantiomeric separation of diniconazole and uniconazole, \(^{116 – 121, 144}\) among others in the analysis of organometallics, \(^{141 – 146}\) and chiral separation of organochloride herbicides\(^{124}\) have been performed by MEKC using SDS micelles with CDs as additives. Optical isomers of silvex herbicides have been separated using in situ charged Deoxy Big CAP micelles.\(^{87}\) Other chiral separations of phenoxy acid herbicides have been accomplished using neutral chiral surfactants such as OG, OM or NG.\(^{125 – 127}\)

MEKC can also provide enhanced resolution of phenols in comparison with CZE. Thus, MEKC using SDS has been employed to separate substituted phenols,\(^{51}\) chlorophenols,\(^{53, 128 – 130}\) and USGS priority phenols.\(^{47, 131}\) A bile salt like SC has also been used as surfactant for a rapid separation of some priority phenols.\(^{61}\) On the other hand, the addition of HP-\(\beta\)-CD in separation buffer with SDS enables the separation of 4-nonylphenol isomers and other alkylphenol homologs.\(^{132}\) However, the separation mechanism of ionizable phenols by MEKC is complicated by the effect of the combined electrophoretic and chromatographic migration on separation. This explains the different elution orders shown in MEKC versus CZE. Although UV detection has been generally employed to determine phenols, a mixture of phenols has been analyzed by indirect fluorimetry\(^{133}\) or amperometric detection.\(^{134}\)

Finally, different types of compounds such as dyes, \(^{135 – 139}\) amines, \(^{140 – 142}\) nitroaromatics, \(^{143 – 146}\) aromatic sulfonates\(^{147}\) and organometallics\(^{148, 149}\) have been separated by MEKC using SDS micelles with or without additives such as organic solvents (acetonitrile, methanol, acetone), urea or CDs (see Table 2). The use of a bile salt like SDC has permitted the enantiomeric separation of 4-nonylphenol isomers and other alkylphenol homologs.\(^{132}\) However, the separation was performed on the basis of differential partitioning of analytes between the two CDs moving relatively, neutral CD (which migrates with the EOF) and charged CD (which migrates with a given electrophoretic velocity and acts as a pseudostationary phase). Mixtures of methyl-\(\beta\)-cyclodextrin (M-\(\beta\)-CD) and sulfobutyl ether-\(\beta\)-cyclodextrin (SB-\(\beta\)-CD) have been used to provide efficient separation of PAH isomers.\(^{155}\) The separation of these isomers using mixtures of \(\alpha\)-CD or \(\beta\)-CD with CM-\(\beta\)-CD was also successful.\(^{156}\) Thus, the 16 PAHs listed by USEPA as priority pollutants have been separated with the system formed by M-\(\beta\)-CD and SB-\(\beta\)-CD\(^{157, 158}\) in less than 20 min.

In microemulsion electrokinetic chromatography (MEEKC), the pseudostationary phase is a microemulsion, that is, an aggregate with a similar structure to that of a micelle, except that it has a core of a minute droplet of oil. Microemulsions are prepared by mixing oil (hydrocarbon), water, surfactant, and co-surfactant (medium alkyl-chain alcohol) in the appropriate proportions. This technique has been studied in comparison

2.3 Other Kinds of Electrokinetic Chromatography

One of the working modes most used in CE is EKC, which includes several techniques with the common feature that separations are based on the partitioning of the analytes between two phases which have different velocities relative to each other. One of the phases is a buffer solution (which migrates with the velocity of the EOF) and the other is a compound distributed homogeneously in the buffer solution, which is strongly electrophoretically retarded and acts as a pseudostationary phase. Micelles are the most used pseudostationary phase (MEKC is one kind of EKC), but other pseudostationary phases such as CD derivatives which have ionic groups, microemulsions, cationic or anionic surfactant monomers, or other alkyl–ionic compounds, which cannot be absolutely classed as micelles, have been successfully employed in EKC for the analysis of environmental compounds resulting in different modes of EKC.

Cyclodextrin electrokinetic chromatography (CDEKC) is a mode of EKC that can employ charged CD or mixtures of neutral and charged CD as the pseudostationary phase. In the first case, the distribution process between the analytes and the CD allows the separation by a host–guest interaction. As an example, cresol isomers have been successfully separated by using a negatively charged CD, carboxymethyl-\(\beta\)-cyclodextrin (CM-\(\beta\)-CD).\(^{154}\) Using neutral and charged CD mixtures the separation was performed on the basis of differential partitioning of analytes between the two CDs moving relatively, neutral CD (which migrates with the EOF) and charged CD (which migrates with a given electrophoretic velocity and acts as a pseudostationary phase). Mixtures of methyl-\(\beta\)-cyclodextrin (M-\(\beta\)-CD) and sulfobutyl ether-\(\beta\)-cyclodextrin (SB-\(\beta\)-CD) have been used to provide efficient separation of PAH isomers.\(^{155}\) The separation of these isomers using mixtures of \(\alpha\)-CD or \(\beta\)-CD with CM-\(\beta\)-CD was also successful.\(^{156}\) Thus, the 16 PAHs listed by USEPA as priority pollutants have been separated with the system formed by M-\(\beta\)-CD and SB-\(\beta\)-CD\(^{157, 158}\) in less than 20 min.
with MEKC using phenol derivatives\(^{(159)}\) and phenylurea and chlorsulfuron herbicides as model mixtures (see Figure 5).\(^{(73)}\) Results have shown that with MEEKC it is very easy to extend the retention window through an increase in the surfactant concentration, and moreover MEEKC provides different selectivities from MEKC.

Finally, in hydrophobic interaction electrokinetic chromatography (HIEKC), the pseudostationary phase can be formed by cationic or anionic surfactant monomers, or other alkyl–ionic compounds in hydro-organic solutions with high concentrations of organic solvent (≥40%). Under these conditions, micelles are not formed because of the high concentration of organic solvent. The separation mechanism is attributed to the hydrophobic interaction between a monomolecular pseudostationary phase and neutral analytes. A series of alkyl aryl ketone homologs\(^{(160)}\) has been successfully separated, in less than 6 min, by HIEKC using phosphate buffer at pH 7.0 with SDS or at pH 2.8 with CTAB as anionic or cationic surfactant, respectively, in 50% acetonitrile. Several mixtures of PAH homologs have been well resolved using a basic buffer (about pH 9) in 40–50% acetonitrile and with tetrahexylammonium perchlorate (five homologs),\(^{(161)}\) or tetraheptylammonium bromide (16 homologs)\(^{(162)}\) or sodium dioctylsulfosuccinate (23 homologs).\(^{(163)}\)

### 2.4 Capillary Electrochromatography

The combination of CZE and HPLC, called CEC, is one of the newest working modes in CE.\(^{(164–166)}\) In CEC, the separation of uncharged analytes is based on partitioning between a mobile phase (buffer which migrates with the velocity of the EOF) and a stationary phase (HPLC material which is static at all times). The stationary phase can be either coating the inner wall of a capillary (open tubular column, OTC) or packing the inner diameter of the capillary (packed capillary column, PCC). The advantage of using EOF\(^{(164)}\) as the driving force is an increased column efficiency because of the flat-flow profile, and moreover, in the case of PCCs the ability to use smaller particles than those used in HPLC (particle diameters as small as 1.5 μm) because EOF is not limited by the column back pressure that results from the passage of a mobile phase through a packed bed, the flow being limited in this case only by the voltage applied. The separation of charged analytes is also possible in CEC, but in this case, the analyte migration velocity will be determined by the partition between the two phases described previously and its electrophoretic mobility. Although two kinds of column can be used (OTC or PCC), most applications have employed PCCs with an ID of less than 100 μm, and these have been commercialized, while OTCs are still in the developmental stage. Generally, PAHs\(^{(167–170)}\) have been used as standards to evaluate OTCs. Some compounds such as PAHs\(^{(171–173)}\) benzene derivatives,\(^{(174)}\) nitrotoluenes and biphenyls\(^{(175)}\) have been utilized to evaluate PCCs. Figure 6 shows an electropherogram of 16 USEPA priority PAHs with a PCC of 75 μm ID and 3 μm octadecylsilica (C\(_{18}\)) particles using a buffer with a high percentage of organic solvent.\(^{(176)}\) Attempts have been made to separate the same mixture of PAHs in HIEKC\(^{(162)}\) and MEKC,\(^{(66)}\) but with poorer results. A linear gradient elution in CEC was used for the separation of 16 PAHs showing a better performance than in isocratic elution.\(^{(177)}\)

It should be emphasized that CEC is still not widely applied owing to the difficulty in manufacturing and operating the PCCs.

### 3 ANALYSIS OF POLLUTANTS IN ENVIRONMENTAL SAMPLES

Most environmental applications in CE are restricted to demonstrations of high-resolution separations with standards of specific pollutants and only a few refer to the determination of pollutants in environmental samples.
There are two main reasons for this. First, CE commercial instruments have been introduced only relatively recently and are not yet in widespread use in environmental analytical laboratories. Second, the sensitivity obtained for the analysis of pollutants by CE has not been adequate for trace analysis. Unfortunately, the injection volumes that can be tolerated in CE without decreasing separation performance, are typically a few nanoliters only. Therefore, although commercial CE instruments equipped with UV absorbance detectors are able to detect quantities as low as several hundred femtograms, very poor sensitivity is obtained as expressed in sample concentration terms (several hundred parts per billion or above $10^{-6}$ M), which are generally at least three orders of magnitude above levels of pollutants in environmental samples (low parts per billion to parts per trillion level). Because the detection ability of commercial CE instruments is far from ideal and they are not sensitive enough to determine compounds in environmental samples, improvements needed to be made to detection systems or preconcentration procedures.

### 3.1 Sensitivity Enhancement Procedures

Several approaches have been developed to improve the limit of detection (LOD) for CE instruments, such as extending the optical path length of the capillaries, using highly sensitive detection systems, and employing several strategies for the preconcentration of samples, namely, solid-phase extraction (SPE), field-amplified sample stacking (FASS), or isotachophoresis (ITP).
3.1.1 Improved Capillary Geometry and Detector Cell Design

Unfortunately, the detection system that can be used in CE, without decreasing the separation performance, is an on-column detection, which implies that the optical path length for detection is limited by the ID of the capillary column. Some authors have extended the optical path length by using Z-shaped flow cells\textsuperscript{179} which improve the LOD by a factor of 20–60, or bubble cells\textsuperscript{84,180} which allow a multiplying of sensitivity usually by a factor of 3–5.

3.1.2 Alternative Detection Systems

Fluorescence detection can provide LODs several orders lower than UV absorbance. In applications of environmental interest the excitation of molecules is done with different lasers in order to achieve very high sensitivities of LIF. Thus, the laser most used in LIF for pollutants analysis is the He–Cd laser (\( \lambda_{ex} = 325 \text{ nm} \)). It is employed (see Table 2) for the determination of hydrophobic compounds with native fluorescence such as aflatoxins\textsuperscript{85} or PAHs\textsuperscript{65,71,81,95,105,157,181–183} in which LODs are \( 10^{-9}–10^{-11} \text{ M} \). However, most environmental pollutants are not intrinsically fluorescent, like some phenoxy acids herbicides\textsuperscript{33,127} which are analyzed by LIF after a derivatization with a fluorophore (e.g. 7-aminonaphthalene-1,3-disulfonic acid (ANDSA)) achieving a LOD around a few parts per billion. The Ar ion laser (\( \lambda_{ex} = 257 \text{ nm} \)) has been employed to analyze 16 USEPA priority PAHs,\textsuperscript{127,157} A semiconductor laser\textsuperscript{105,184} has also been employed for detection of PAHs obtaining worse sensitivity (LOD \( 10^{-8} \text{ M} \)) than with a He–Cd laser. Finally, another alternative for nonfluorescent analytes is the use of indirect LIF detection. This detection is the result of the decreased signal from a fluorescing reagent present in the running buffer, which is caused by the displacement of the reagent with nonfluorescing analytes. Indirect LIF detection was employed in the separation of six aromatic compounds,\textsuperscript{185} two neutral herbicides,\textsuperscript{86} 11 USEPA priority phenols\textsuperscript{186} and a mixture of phenols (phenol, 1-chlorophenol and cresol isomers),\textsuperscript{133} LODs for these compounds were in the \( 10^{-6}–10^{-7} \text{ M} \) range.

MS is one of the most powerful detection methods for obtaining structural information on separated analytes. Recently, capillary electrophoresis/mass spectrometry (CE/MS) has been recognized as a promising technique for analysis of mixtures of pollutants. Thus, sulfonylurea herbicides have been analyzed by CZE using ion spray MS.\textsuperscript{126} Moreover, aromatic amines have been analyzed by MEKC using an electrospray-chemical ionization interface.\textsuperscript{140} However, some problems still exist in CE/MS. This detector has relatively poor concentration sensitivity. The use of nonvolatile buffers is generally avoided (composition of buffer must be chosen previously). On the other hand, the coupling of MEKC with MS is difficult owing to the presence of high concentrations of micelles in the running buffer, which can cause low ionization efficiency. Nevertheless, current research is rapidly changing this situation by developing new CE/MS interfaces, and novel pseudostationary phases.

Amperometric detection is advantageous because LOD should not increase with a decrease in the ID of the capillary column as occurs with UV detection. However, this type of detection has been scarcely used in CE, particularly in the analysis of environmental pollutants, owing to its difficult manipulation and to the limited number of pollutants with electroactive character. Actually, amperometric detection has been used for the analysis of phenols\textsuperscript{134,187} and chlorophenols\textsuperscript{188} reaching a LOD close to \( 10^{-8} \text{ M} \).

3.1.3 Preconcentration by Solid-phase Extraction

Liquid–liquid extraction (LLE) and SPE are the most common methods for liquid sample enrichment. However, this method but with recognized disadvantages: it is laborious, time consuming and subject to problems such as the emulsification of the samples during extraction and the disposal of large volumes of toxic solvents. Thus, trace enrichment of environmental samples in CE analysis is preferably performed via SPE (see Table 3), providing concentration factors of \( 10–10^5 \), and being especially effective for aqueous samples. In off-line SPE, large-volume samples are passed through a small cartridge packed with sorbent. Analytes are trapped by the sorbent and then eluted with a small volume of a suitable solvent. An alternative technique based on the SPE principle but with a piece of sorbent membrane disk to replace the SPE cartridge has been reported.\textsuperscript{189} Because the sorbent disk has a larger contacting area than a SPE cartridge, larger flow rates are permitted, and therefore the extraction for large-volume (1 L or more) samples can be performed in much shorter times than with a SPE cartridge. Nevertheless, with the off-line preconcentration technique, the sample is not introduced directly into the capillary, requiring major handling of the samples and analysis time. For this reason, an on-line coupled SPE/CZE has been described\textsuperscript{29,190} using a reversed-phase coated capillary column to perform SPE preconcentration before CZE separation. However, owing to the small amount of reversed-phase coating on the inner wall of the capillary, the breakthrough volumes and the capacity, and hence the enrichment factors, are rather limited (10–35-fold). This is why on-line SPE is used with a short plug of

* Capillary length to the detection. MHEC, methylhydroxyethylcellulose.
a reversed-phase material (particles) which is packed at the beginning of the separation capillary. These capillaries have a somewhat higher capacity and will show higher breakthrough volumes and enrichments (up to 100-fold). However, the main disadvantage is that these capillaries are only available from a limited number of suppliers, and are much more expensive (at least 30 times) than the simple fused-silica capillaries commonly used in CE. In addition, an environmental sample can almost never be directly introduced because the system could suffer plugging and severe contamination. Therefore, the sample must be cleaned or extracted and should not contain a high percentage of organic solvent.

3.1.4 On-column Preconcentration by Field-amplified Sample Stacking

FASS occurs when the injected sample has a lower ionic strength than the running buffer. Then, an analyte ion dissolved in the sample matrix will experience locally an increased field strength and will migrate with a higher velocity. When the analyte reaches the boundary between the sample matrix zone and the running buffer, it will slow down again and stack into a zone much shorter than the original sample zone, thus the analyte has been preconcentrated or focused on-column. Cationic compounds are focused at the front of the sample zone and anionic compounds at the back of the sample zone.

In the simplest form of FASS, a plug of sample (dissolved in diluted buffer or in water) with a very short length compared to the total length of the capillary, is introduced hydrodynamically into the capillary. In this case, LODs can be improved by a factor of 10. However, when attempting to inject a larger volume of sample, a laminar flow occurs and destacks the stacked analyte ion. Fortunately, Burgi and Chien provided a simple method for removing the relatively large sample matrix zone during or after the enrichment step, but before the CZE separation started. This can be accomplished by pumping out the matrix zone, using the EOF. For anionic analytes, this involves field polarity reversion after the capillary is filled with the sample, but for cationic analytes, this demands a reversed EOF. Therefore, the enrichment factor attainable by field amplification can also benefit from the EOF and LODs can then be improved by a factor of 200. The same technique can also be performed by electrokinetic injection with LODs improved by a factor of 1000. However the reproducibility is poor.

FASS can be also used in MEKC. For ionic analytes, the procedure is the same as that for CZE. However, for neutral analytes the procedure involves dissolving them in a micellar solution with a low concentration just above the CMC. Then, the micelles will be stacked up under applied voltage and will cause stacking of neutral analytes.

3.1.5 On-line Preconcentration by Isotachophoresis

ITP is a working mode in CE which is performed in a discontinuous buffer system. The analyte ions of an injected sample migrate between a leading buffer having the highest mobility and a terminating buffer having the lowest mobility. When voltage is applied, the analyte ions will be focused and migrate as consecutive zones, according to their mobility, between the leading and terminating buffers. From the point of view of trace analysis, on-line coupling of ITP and CZE is very attractive because it reduces the LOD by a factor of $10^3 – 10^4$. However, this technique has seldom been employed in environmental analysis (see Table 3) because it requires complicated instrumentation.

ITP can be also performed before CZE separation as an ITP-like state realized only for a limited period of time (transient-ITP preconcentration step). Transient-ITP is possible when the sample contains an excess of a matrix ion with higher electrophoretic mobility than analytes, and at the same time, the CZE electrolyte has a lower mobility than analytes. In this case, the matrix ion can act as a leading buffer and the CZE electrolyte as a terminating buffer. This technique can be used in commercial CE instruments by carefully selecting the CZE electrolyte to form an ITP buffer system and it could reduce the LOD by a factor as high as 200 when analytes migrate just behind the matrix ion. However, as in ITP, there are some disadvantages:

1. It might be difficult occasionally to find a suitable combination of leading and terminating buffers.
2. The migration times of analytes in unknown samples may be hard to predict.
3. Irreproducibility of EOF will give bad enrichment performance.

Finally, the enrichment procedures described above (FASS and ITP) can be problematic in some environmental samples where matrix components may also be concentrated; significant background matrix may degrade separation and mask the analytes of interest. Another drawback is that concentration enhancement can be reduced, eliminated or even reversed when the sample has a relatively high electrolyte content, because the sample zone may broaden, decreasing the separation efficiency and then the concentration sensitivity may decrease significantly. To resolve these problems, some authors employ a sample preconcentration technique like SPE coupled with FASS or with ITP/CZE for separating some pollutants. Such combination allows

Relative absorbance

CE has been employed to analyze pollutants in environmental samples and environmental matrices spiked
with standards. Table 3 shows experimental conditions
employed to analyze these compounds arranged alphabetically.
MEKC has been employed to determine hydrophobic
compounds such as aflatoxins. High-speed separation of
four aflatoxins in less than 30 s was optimized.181/ and
a bile salt such as SDC was used with acetonitrile as
additive. This separation coupled with an on-column
LIF detector allows LODs in the range 0.05 – 0.9 fmol
for underivatized aflatoxins. This method was applied
to the analysis of a spiked (16 ppm) corn meal extract
obtained by SPE..181/ Amines from groundwater and soil
samples preconcentrated by off-line SPE have been easily
analyzed by CZE based on their positive charge in acidic
solution..192/
Dyes and pesticides can be separated by both CZE
and MEKC. In the case of seven monosulfonated
dyes.138/ from spiked water and soil samples, MEKC
was selected for its better selectivity. On the other hand,
the potential and drawbacks of CE for the monitoring of
pesticides water pollution have been discussed..195/ CZE
has been employed primarily.193 – 199/ (seven of ten works
in Table 3), although MEKC has also been used..200 – 202/
UV detection was used in all cases (Table 3) and
different sample treatments (off-line SPE, FASS and ITP)
were employed. Figure 7 shows the electropherogram
corresponding to a Rhine river water sample spiked
with 5 ppb of four herbicides, two of them chiral, by
using CZE and a derivative of b-CD as chiral selector
in the separation buffer (sample volume 20 mL)..193/
In Figure 8, the versatility and efficiency of MEKC in
the separation of 11 herbicides from distilled water are
shown. In the same electropherogram, ionic herbicides
and various nonionized herbicides are separated in a
short analysis time..195/
Other pollutants such as nitroaromatic and organometallic compounds have been determined by MEKC in
heavily contaminated soil samples and in water samples,
respectively. Because the concentrations of nitroaromatic
compounds were relatively high (soil from military zones),
the analysis was accomplished by MEKC with UV
detection without preconcentration..203/ The possibility
of determining organolead and organotin compounds in
other environmental samples such as drainage and tap
waters has also been demonstrated..204/ Figure 9 presents

MEKC with SDS and diode-array detection\(^{(106)}\) and 16 USEPA priority PAHs contained in an extract obtained by supercritical fluid extraction (SFE) of a contaminated soil sample were determined by CDEKC using a mixture of charged and neutral CDs and LIF detection (\(\lambda_{\text{ex}} = 325\) nm).\(^{(157)}\)

CZE has been used to determine several chlorophenols in different water samples.\(^{(180,188)}\) The fact that phenols respond to a sensitive detection method such as electrochemical detection has allowed determination of seven chlorophenol isomers and three neutral phenols in industrial wastewater by CZE with on-column electrochemical detection (see Figure 10).\(^{(188)}\) LODs in the picomole range were achieved by thermostating the separation capillary and no interference from the impurities present in industrial wastewater samples were observed, using only a simple LLE with chloroform–diethyl ether. Therefore, the use of an electrochemical detector provides excellent sensitivity and selectivity without derivatization. Thus, the separation of 11 USEPA priority phenols by CZE with on-column amperometric detection has been successfully applied to the analysis of industrial wastewaters.\(^{(187)}\) In order to minimize the large electrophoretic currents, which seriously interfere with amperometric detection, CHES was used as the running buffer because of its

the separation by MEKC of the most common organolead and organotin compounds (trimethyltin, trimethyllead, triethyllead and tributyltin) in the extracts from 1 L of rain water samples after disk SPE extraction. In addition, CDMEKC was also applied to separate two organolead and two organoselenium compounds from water samples using LLE for sample enrichment.\(^{(148)}\)

PAHs have been analyzed in contaminated soil samples by different kinds of EKC and detection systems. Thus, several PAHs were determined in an extract of creosote-contaminated soil by MEKC with a bile salt and UV detection at 214 nm.\(^{(61)}\) Quantitation of seven PAHs in soil samples contaminated with a mixture of standard PAHs and machine oil was carried out by

**Figure 10** Electropherogram of an industrial wastewater sample obtained by CZE with electrochemical detection. Peaks: (1) phenol, (2) 2-chlorophenol (concentration, 50 ng mL\(^{-1}\)), (3) 4-chlorophenol, (4) 2,4-dichlorophenol, (5) 2,6-dichlorophenol, (6) \(o\)-phenylphenol, (7) catechol, (8) 2,4,6-trichlorophenol, (9) 2,3,4,6-tetrachlorophenol, (10) 4,5,6-trichloroguaiacol, and (11) pentachlorophenol. Conditions: separation media, 0.045 M dihydrogenphosphate/0.015 M borate buffer (pH 8.0), capillary tube, 25 \(\mu\)m ID \(\times\) 65 cm (30 cm to the detector), electrokinetic injection, 20 kV \(\times\) 30 s, applied voltage, 20 kV; amperometric detection using a carbon fiber at +1.4 V versus SCE (standard calomel electrode); temperature, 20–25°C. (Reproduced by permission of Elsevier Science Publishers. Copyright (1990) from C.D. Gaitonde, P. Pathak, J. Chromatogr., 514, 389–393.\(^{(188)}\))
zwitterionic nature. The analysis of similar samples was achieved by CZE with indirect laser-induced fluorescence detection. This detection technique involves the addition of a noninteracting and fluorescing ion to the running buffer to create a constant fluorescence background and when a charged analyte is present, it displaces the fluorescing ion of the same charge owing to local charge neutrality, resulting in a decreased background signal even though the analyte does not absorb or fluoresce.

Finally, other pollutants separated by CE were sulfonates, which were analyzed by MEKC with UV detection in spiked river samples or by CZE with LIF detection in unspiked river samples.

In general, Table 3 shows that the analysis of pollutants in environmental samples can be resolved by two means: (i) sample preconcentration with off-line SPE (principally with a C18 disk), or (ii) use of detectors with enough sensitivity (LIF or amperometric detection). In both cases, it is possible to obtain a LOD of about $10^{-9}$ M which is adequate for the determination of pollutants in several environmental matrices or samples.

4 CONCLUSIONS

CE is a newly developed separation technique, which has demonstrated its enormous capability and potential for separating ionic and neutral solutes owing to its simplicity and high efficiency. The first option for analyzing ionic or ionizable compounds by CE is CZE with or without additives to increase separation selectivity. When this selectivity is poor or the compounds to be analyzed are not ionizable, separation by CE should be achieved by means of MEKC with or without additives to improve separation resolution. Finally, other kinds of EKC or CEC can be used to enhance the separation or decrease the analysis time.

CE is very suitable for those analytes that are not amenable to GC (polar and acid or basic pollutants, e.g. modern pesticides in aqueous samples) or when existing HPLC methods do not offer sufficient separation power. Many efficient and rapid CE separations of standards, including compounds of environmental interest, have been described. Despite the excellent prospects for CE, the analysis of pollutants in environmental samples where these compounds are at trace level (governmental regulations require determination of lower and lower levels of pollutants in environmental samples) requires the use of enrichment procedures or highly sensitivity detectors. Off-line extraction, pre-concentration techniques and special injection methods are being developed. A simple clean-up, followed by a large-volume injection and a high-efficiency separation in a CE system, should be adequate to fulfill the requirements of real-life environmental applications. Several research groups are developing their own highly sensitive detectors such as LIF, which has become popular mainly because of its capability to provide extremely high sensitivity ($10^{-12}$ M). Unfortunately, this type of detector is not generally applicable in environmental analysis. Many interesting pollutants cannot be derivatized using any of the few fluorescence labels which match the particular laser lines. Other sensitive detection systems, such as laser-induced resonance energy transfer, chemiluminescence and inductively coupled plasma MS are being developed. With respect to MS which is one of the most powerful detection systems, current research is devoted to developing new CE/MS interfaces in order to increase the possibility of CE/MS being able to solve problems in environmental analysis.

Concern for the environment is not limited to ecological aspects, but encompasses matter such as the origin and the effects of pollutant discharges, the evaluation of environmental programs, quality control and quality assurance related to analytical procedures, and the analysis of the content of environmental matrices – both inorganic and organic – in order to control and evaluate environmental pollution. Thus, it is right to say that analytical chemistry has an important role to play in environmental analysis.

A large number of analytical methods are used in environmental analysis. Some are widely used in environmental programs, and are reference/standard/official methods for the analysis of a great variety of compounds.

However, there is no single universal procedure that can be applied to the analysis of any chemical species in any environmental matrix, and for any in situ/remote measurement.

Electrochemical (EC) methods are widely used to investigate environmentally significant compounds, both organic and inorganic. EC research covers all important branches of environmental analysis, such as in situ/remote measurements, flow systems, combined applications with a separation technique, (bio)sensors for selective analysis, and monitoring and control procedures.

This article discusses the application of these EC methods to the study of organic compounds occurring in environmental water and waste samples.

1 INTRODUCTION

Modern EC methods are applicable to a very large number of organic compounds of great importance, not only in environmental monitoring but in many other fields.\(^1\)

Most applications of chemical analysis to environmental protection involve trace determinations; consequently, highly sensitive methods that offer good selectivity, precision, and accuracy are needed. Other desirable characteristics are easy sample pretreatment, quick analysis, easy automatization of the method, the availability of a portable device for field measurements, low cost of instrumentation and analysis.\(^2\)

Assignments given to environmental analysis include:

- the quantitative and qualitative control of pollutant emissions in the environment; the elucidation of the path of the emitted pollutant from its source to its interaction with humans; the monitoring/study of the conversion and transformation of pollutants as well as their natural reactions; and the discovery and elucidation of processes for the prevention of the emissions or processes for their neutralization. Unfortunately, it is impossible to monitor the content, distribution and fate of all chemical substances present in the environment, whether man-made or naturally occurring.

Polarography was one of the first techniques for monitoring some anthropogenic pollutants at the trace level in real environmental samples, in particular for heavy metals. Nowadays, EC methods have to compete with other methods – the whole analytical procedure, from problem definition to data evaluation, must be taken into account when choosing the right determination method. Economic aspects are also very important, and include the cost of instrumentation, the qualification and number of operators, sample requirements (such as the sampling method, necessity and manner of storage), and the possibilities and difficulties of the process automatization;\(^3\) of increasing importance for
environmental monitoring is quality assurance and quality control.

A large number of important organic environmental compounds are electrochemically active, either directly or indirectly. In most cases, the sensitivity is adequate for organic environmental analysis; the use of stripping techniques, especially adsorptive stripping analysis for organic compounds, increases this sensitivity. Selectivity is limited by several factors, such as the number of compounds that are active in a same range, the overlapping of signals, and surface alterations of the electrodes. Using chemical reactions it is sometimes possible to achieve experimental situations to solve most problems without using special separation techniques. However, in many organic analyses the variety of compounds is much larger, and similar compounds are only badly or not distinguished at all by their EC properties. For these more complex problems, the use of EC sensors after high-performance liquid chromatography (HPLC) or other separation technique offers an attractive solution. Although EC methods have a moderate equipment cost, the whole analytical process must be priced for a particular sample. Experienced staff are also necessary for the accurate analysis of complex environmental samples when using modern methods and instrumentation for EC trace analysis.

In voltammetry, a continuous changing potential is applied and the current that flows is continuously recorded; the term ‘polarography’ is reserved for voltammetric methods in which an electrode with a renewed surface is used. The most-used techniques for analytical purposes are cyclic, differential pulse, and square wave voltammetry. Potentiometry involves the measurement of the potential of a working electrode (WE) as a constant current is passed through an EC cell; sensors based on MOSFET (metal oxide semiconductor field effect transistor) semiconductors is a developing field in potentiometry. Phenomena at an interface between a solution and an electrode can be exploited for potentiometric, coulometric, and voltammetric detectors. Coulometric detectors are based on the measurement of the electrolyte under zero current conditions. With voltammetric detectors, the current is measured as a function of an applied potential. Amperometric, pulsed amperometric, and scanning voltammetric detectors are all classified as voltammetric detectors. In coulometric detectors an electrode reaction efficiency of practically 100% is obtained.\(^{(4)}\)

Separation techniques can also be used for preconcentration and enhancement of sensitivity, and thus lower detection limits can be obtained. Although stripping techniques involve a preconcentration step, the separation is usually a secondary effect as the aim of stripping is to improve the sensitivity of the determination.\(^{(5)}\)

The most important EC methods applied to environmental analysis are based on the measurement of signals due to phenomena at an interface between an electrode and a solution. However, there are some problems associated to this superficial interaction. The sensitivity of electrode interfaces in stripping methods, with respect to the adsorption of interferences or surface alterations, is the main source of problems for their application to real environmental samples. This is particularly true in the case of incomplete destruction of organic matrix components. Selectivity is limited in voltammetry because of overlapping voltammetric signals. One of the most critical aspects of the routine analysis of complex environmental samples is the stability and reproducibility of the WE surface. The use of renewable mercury electrodes avoids this problem, but its toxicity is an increasing matter of concern; solid electrodes with stable and reproducible surfaces are a very interesting field where very important progress is being made.

The application of EC (bio)sensors is a possibility, due to several characteristics, such as intrinsic specificity, fast analysis, and minimal requirements for sample treatment. However, widespread application of EC (bio)sensors for environmental purposes is remains limited by the low stability of (bio)sensors and their high detection limits.\(^{(6)}\) EC (bio)sensors can be useful for field monitoring, to provide enough information for the routine testing and screening of samples. In this way they can be used to establish an unmanned measuring system for the continuous monitoring of the environment at selected sites, or used as a component of a portable instrument for incorporation in flow systems.\(^{(7)}\)

In situ measurement offers several advantages. The operations connected with the collection, transport and storage of samples are eliminated, and so the cost of the global process is lower, and the delay and
error incurred in such operations can be avoided. The measurements are carried out in real time and the pollutant is analyzed in its own environment. The results are obtained quickly, and consequently the problem can be solved promptly. Remote EC sensors for monitoring organic pollutants are a very interesting field, and advances in EC technology now enable the use of modified electrodes, ultramicroelectrodes, the design of highly selective recognition layers, sensor arrays, and development in the areas of microfabrication, flow detectors, and compact, low-powered, user-friendly instrumentation.\(^8\)

### 2 SAMPLE PREPARATION

The use of analytical procedures applied to environmental analysis involves a succession of steps, including: sampling and storage of environmental samples; the collection of treatments that must be carried out on the sample for quantification; and final determination and presentation of results. Several operations can be considered of general application to most procedures. After sampling, samples are filtered, usually through a 0.45\(\mu\)m filter, and stored in the dark at 2–4°C. After treatment, and when a chromatographic system is used, evaporation of the solvent prior to chromatographic analysis is carried out, in order to reduce the sample to an appropriate volume for injection. Most analytical papers dealing with environmental applications include an exact procedure for the sample treatment.

In environmental analysis, the analyzed species are seldom accessible directly to the detector. Treatment procedures include digestion, extraction and separation steps, which can add considerable uncertainty to the overall results. Matrix influences also have to be evaluated. The inestability of the analyte in the sample must be considered. Due to the high ionic content of some samples it is advisable to determine several species directly, as in seawater. Sometimes it is necessary to form a derivative which can be determined electrochemically.

Usually, UV (ultraviolet) digestion by sulphuric acid/hydrogen peroxide or by microwave digestion is used. In the analysis of organic pollutants, when water samples are too complex and/or the analytes very diluted, preliminary preparation prior to the analysis is needed. Traces of organic pollutants must be extracted from aqueous media and concentrated, and other components which can also be co-extracted and co-concentrated, and which may interfere in the analysis, must be removed from the matrix. The most usual methods for extraction and concentration of organic pollutants are liquid–liquid extraction (LLE) and solid-phase extraction (SPE).

The LLE technique has been used for many years due to its simplicity and good results. If a nonpolar solvent is chosen as the extractant, the addition of a supporting electrolyte is necessary to ensure a solution of sufficient conductivity before EC determination. The popularity of SPE has increased because of the reduced use of organic solvents. Micro-LLE is always an attractive solution. In the field of SPE, new sorbents are being developed in order to improve the selectivity in this preliminary step, to enable subsequent steps of removing interferents to be eliminated or simplified.\(^9\)

Even though separation techniques are somehow always undesirable, because they will always increase the amount of labor and cost of the analysis, in many cases their application is necessary to reduce interference and/or to increase the sensitivity of the method by preconcentrating the analyte.\(^5\) Environmental analysis includes the use of flow systems coupled to separation methods, such as chromatography, with ED for the analysis of complex environmental samples. As chromatography is only a way to separate compounds from each other, it is necessary to use a detector which is sensitive to the separated compound. For organic analysis, the most common EC measuring technique in chromatography is amperometry, though some others detectors, such as coulometric, potentiometric, pulsed amperometric and scanning voltammetric detectors are also used.

The combination of capillary electrophoresis and electrochemistry is a developing field within EC research, and has been used for the analysis of catecholamines, carbohydrates, amino acids, chlorophenols and explosive compounds.\(^10\) ED appears to be promising for analysis of compounds with well-defined redox behavior. Capillary electrophoresis has a high resolution, is suitable for ionic/polar and apolar compounds, but has a low loading capacity, in the range of few nanoliters; this last characteristic is not a disadvantage for very sensitive techniques. Table 1 gives several examples of the preparation/treatment/extraction procedures used with environmental samples.

### 3 ENVIRONMENTAL APPLICATIONS

The number of papers related to EC methods applied to environmental analysis is increasing. Different matrices, compounds and specific strategies of analysis have been reviewed to provide a general view of the applications of these methods. Analytical techniques for the determination of chemical species in natural water, drinking water and wastewater have been summarized, including EC methods.\(^39\)

In general, the sensitivity required in the determination is not a restriction when EC methods are

applied to the analysis of organic pollutants. Detection limits obtained with these methods compare well with those obtained by other methods; several papers describe comparative studies between ED and other detectors.

Problems associated with possible interferences are, sometimes, particular when EC methods are used. It is known that selectivity of some EC applications is poor. Many organic pollutants have similar molecular structures. Therefore, the use of an unspecific electrode without a previous separation step results in the overlapping of the redox responses of similar compounds when their mixtures are analyzed. It is difficult to find a specific reaction or specific substrate electrode for each organic compound.

Most EC processes used in environmental analysis take place on an electrode surface, so reproducibility and stability of the active surfaces is an important consideration. Unfortunately, these characteristics are not easy to achieve. As a result of the problems associated with the use of mercury electrodes, most research deals with new and more sensitive combinations of EC detectors and separation techniques, specific (bio)sensors for organic pollutants, and the stabilization of electrode surfaces.

Trace organic contaminants in surface water have been considered. The methods described in literature or used in laboratories often derive from those used for drinking water, with additional treatments. There is a general trend to develop LC methods, due to their advantages over gas chromatography (GC) for a large
number of organic pollutants. EC methods for the determination of anilines and chloroanilines are described, with detection limits below 0.1 µg L⁻¹.

As most applications use a separation step combined with ED, there are reviews that discuss the advantages and limitations of combining separation technique and voltammetry,⁵³ as well as reviews that describe the EC detectors used for LC and capillary electrophoresis.⁴⁴ Different types of detectors are considered, and much effort is directed at overcoming the difficulties of using combined techniques to achieve selective determinations.

Biosensors offer many possibilities for the analysis of organic pollutants. Despite the problems associated with biosensors, their attributes, such as selectivity, in situ/remote measurements, and minimal requirements for sample analysis are very important, and research in this field is increasing. Although amperometric and potentiometric transducers are used,⁴¹ an electrical transducer and a potentiostat can also be used for detection. Most reports refer to amperometric biosensors, because they offer higher sensitivity and selectivity. Although potentiometric devices are not used as much, they still make an important contribution. For example, an enzyme (cholinesterase) potentiometric biosensor can be used for preliminary testing of the total pollution of domestic and industrial discharges.³²

The most used biosensors are tyrosinase based and peroxidase based. Environmental organic pollutants are either enzyme substrates or enzyme inhibitor, for both types of biosensors.⁴⁵ Whereas thioureas, mercaptoethanol, hydroxylamine, methylisothiocyanate, and cyanide are detected with a peroxidase biosensor, carbamates are detected with a tyrosinase biosensor. The use of cholinesterase-based biosensors has also been described.⁴⁴ These biosensors are applied to the analysis of organophosphate and carbamate pesticides; acetylcholinesterase and butyrylcholinesterase are the enzymes used for the analysis of pesticides in real environmental samples. Potentiometric or amperometric transducers can be used for the analysis of these pesticides. Most potentiometric enzymatic biosensors are based on the immobilization of an appropriate esterase and measurement of the pH change which is produced; a glass electrode or a pH-sensitive ion-sensitive field effect transistor (ISFET) is usually used as the internal detector for the pH change.⁴⁵ Different amperometric transducers are employed. They use the reduction of oxygen, or the oxidation of hydrogen peroxide or thiocholine. In general, amperometric detection reaches lower detection limits than potentiometric detection.⁴⁶

EC immunoassays are based on modifications of enzyme immunoassays (EIAs) and the enzyme activities are determined potentiometrically or amperometrically. Some EC immunosensors have been described, including one for the analysis of PCBs using a conducting polymer-based immunosensor.⁴⁷

Among specific strategies, a review on developments and applications of screen-printed EC sensors and their applications to environmental analysis can be found.⁴⁸ Several analytes have been studied in environmental samples, and the research focuses on obtaining portable devices and the ability of performing environmental analysis away from a laboratory. Amperometric biosensors have been applied to hydrazines, hydroquinona, phenols and pesticides. Two interesting alternatives are the use of remote sensors and submersible probes for organic analytes, by appropriate modification of the surface of the electrode and deposition of chemical recognition layers.⁸ Phenolic compounds belong to a very important group of organic pollutants. The EC literature on these compounds is wide, and the methods developed for their determination include EC detectors coupled to separation techniques, amperometric (bio)sensors, and remote measurements. Methodologies for the determination of phenolic compounds in some water types have been reviewed including ED, amperometric biosensors, and emerging techniques.⁴⁹ Applications of EC methods to the determination of other groups of organic pollutants in environment have been also described, such as organoarsenic and organotin compounds.⁵⁰ surfactants,⁵¹ ethylenediaminetetraacetic acid (EDTA)/diethylenetriaminepentaacetic acid (DTPA).⁵²

4 ENVIRONMENTAL REGULATIONS AND METHODS

In spite of the proven applicability of EC methods for organic analysis, there are few examples of EC methods being used as reference and/or official methods for the organic analysis of environmental samples.

Most current official analytical methods are based on LLE followed by GC using different detectors, such as electron capture and mass spectrometry (MS). However, there is a general trend to change these procedures to SPE followed by HPLC.⁴⁹

The methods for organic chemical analysis of municipal and industrial wastewater, used by the United States Environmental Protection Agency (USEPA), include HPLC with an ED procedure for the determination of benzenes at a glassy carbon electrode, or equivalent. An LLE procedure is used in the sequence chloroform–acid–chloroform; the final chloroform extract is exchanged to methanol while it is being concentrated using a rotary evaporator for introduction into the HPLC system. Detection limits of 0.08–0.13 µg L⁻¹ are reported.⁵³
Polarography has been proposed as an official German standard method for nitrilotriacetic acid determination in water, wastewater, and sludge.\textsuperscript{1} The German ESB (environmental specimen banking) programme includes the regular determination of a wide variety of organic and inorganic species; electroanalytical methods and other analytical techniques are used to carry out these determinations.\textsuperscript{1}

European Community Directive 76/464/ECC lists organic compounds to be eliminated from discharges. The drinking water standard methods are described in Directive 79/869/ECC. These methods are chemical group-specific analytical parameters, and nowadays are insufficient for the analysis of pollutants in water samples of different nature and origin. For example, nonionic surfactants are determined from potentiometric measurement after precipitation with bismuth. Many of the newly developed methods have been derived from those used for drinking water. So, a selective preconcentration technique has been described for the analysis of anilines and chloroanilines coupled to an oxidative ED; these highly toxic substances are included in Directive 76/464/ECC, and their determination is possible thanks to the selectivity of the procedure. River water samples are analyzed, and detection limits below 0.1 $\mu$g L$^{-1}$ are reported.\textsuperscript{46}

\section*{5 METHOD DEVELOPMENT}

\subsection*{5.1 Nitrated Organic Explosives Components}

Nitrated organic compounds have been widely used as munitions components; they have been produced in large quantities, and have to be regulated by environmental agencies.

There are several reasons for the great interest in the determination of organic explosives. First, their inherent toxicity; moreover, some of the biotransformation products, mainly aminoaromatic compounds, are known or suspected carcinogens or mutagens. Second, the localization of these explosives; surface and groundwater are generally contaminated by explosives in the vicinity of former ammunition plants, and decommissioning of military bases for other uses must be accompanied by verification that all pollution has been removed. Table 2 shows the application of EC methods to the analysis of nitrated organic explosives in environmental samples.

An HPLC method with UV and ED is described for monitoring the degradation of organic explosives. Amino and phenolic compounds are determined by oxidative ED (+1.1 V) at a glassy carbon electrode, whereas UV detection is used for nitro compounds. The samples (groundwater taken near a former ammunition plant) is injected directly in the HPLC system. To achieve the degradation of the explosives, samples are exposed to daylight for different periods of time.\textsuperscript{11} Figure 1 shows the effect of light exposure on water samples for different periods of time.

The use of hanging mercury drop electrode (HMDE) and the mercury film electrode (MFE) have been described for the reductive ED of organic explosives.\textsuperscript{56,12}

Well and surface water samples are collected, and two different extraction techniques are used, LLE and SPE. The extract is injected in an HPLC system with reductive ED (−1.0 V) at a MFE.

A glassy carbon WE in an HPLC system with ED allows the application of both reductive and oxidative detection.

\hline
\end{tabular}
\caption{Environmental analysis of nitrated organic explosives by EC methods}
\end{table}

\textsuperscript{a} Value for oxidative mode; for reductive mode, 5–10 times higher detection limits are obtained.
Nitroaromatics, nitramines, aminoaromatics and nitrophenols were determined in groundwater samples from the surroundings of a former ammunition plant, and the results compared with those obtained by UV detection. A two-step LLE procedure is used: dichloromethane at pH 9 to obtain the neutral/basic fraction, and at pH 2 for the acidic fraction.\(^\text{(13)}\)

Electrokinetic capillary electrophoresis with amperometric detection has been used for the determination of organic explosives.\(^\text{(10)}\) ED is carried out by a silver-on-gold electrode at \(-0.7\) V. A groundwater sample obtained in the vicinity of the remediation site is used as sample. Detection limits in the range 70–110 \(\mu\)g L\(^{-1}\) were found for all explosives, lower in all cases than with UV detection. Excellent agreement was found between the results obtained by capillary electrophoresis with amperometric detection and the standard USEPA method.

A remote EC sensor reported by Wang et al.\(^\text{(57)}\) allows the continuous monitoring of the explosive 2,4,6-trinitrotoluene. Square wave voltammetry as the EC...
technique, and a submersible carbon-fiber as the WE are used. The electrode is connected to a 50 ft shielded cable. The response is very selective due to the low detection potential for the explosive. Low mg L$^{-1}$ detection limits are obtained for untreated river water, groundwater and drinking water spiked with 2,4,6-trinitrotoluene.\(^{[57]}\)

### 5.2 Aromatic Amines

Amines are present in the environment at the trace level. They enter the environment from a variety of sources, such as industrial discharges, from pesticide degradation, or from bacterial conversion of azo compounds into the precursor amines.

Aromatic amines are included in the EPA list of priority pollutants. The EEC directives give a concentration limit of 1 μg L$^{-1}$ for all aromatic amines in drinking water, and 0.5 μg L$^{-1}$ for the concentration of individual compounds. Table 3 shows the application of EC methods to the analysis of aromatic amines in environmental samples.

LC with ED has been described for the analysis of aromatic amines as these compounds are easily oxidized. Different aqueous environmental samples have been analyzed using LC or HPLC,\(^{[15,58]}\) and a potential in the range 0.4–1.0 V is usually required together with previous sample preconcentration.

Cyclic voltammetry and hydrodynamic voltammetry can be used to study the voltammetric characteristics of these compounds. Aromatic diamines have a significantly lower oxidation potential than the monoamines, so the applied potential can be used for the individual analysis of aromatic mono- or di-amines.\(^{[59]}\)

The UV detection limits at 235 nm and for ED at 0.9 V are always below the regulatory limits. Although UV detection can be used alone, ED provides complementary information for identification of the analytes.\(^{[14]}\)

The use of DNA recognition layers has enabled the development of a DNA-modified electrode for detection of toxic aromatic amines.\(^{[60]}\) It can be used as a screening tool for these compounds.

### 5.3 Other Nitrogen-containing Compounds

An amperometric sensor for flow injection analysis (FIA) of hydrazines has been developed; the electrode is a Nafion–ruthenium(III) modified glassy carbon electrode for the study of electroxidation of hydrazine compounds.\(^{[61]}\) EC oxidation of hydrazine catalyzed by 4-hydroxy-2,2,6,6-tetramethyl-piperiminoxy at a glassy carbon electrode has also been applied to waste and river water.\(^{[62]}\)

For hydrazines, a DNA-coated carbon paste electrode has been used as a sensitive biosensor for the detection of hydrazine compounds, by means of potentiometric stripping analysis. DNA immobilization is carried out at 1.7 V; for measurement, a stripping current of 8 μA is used.\(^{[63]}\) Sensors for field monitoring studies are always an important trend in environmental analysis. A remote EC sensor for field monitoring has been described for hydrazine, based on a catalytic film of 3,4-dihydroxybenzaldehyde. The electrode is coupled to a shielded cable for remote operation.\(^{[64]}\)

Capillary electrophoresis with ED has been used for the analysis of hydroxylamine. An ultramicro palladium particle modified carbon fiber electrode was employed and applied to the analysis of river and wastewater.\(^{[65]}\)

Polarography of nitrilotriacetic acid complexed with Bi(III) is widely applied to verify the pollution of waters.\(^{[66]}\)

A correct determination of nitrilotriacetic acid in the presence of Fe(III) and Al(III) has been described, and applications to natural and wastewaters have been carried out. Tables 3 and 4 show applications of EC methods to the analysis of hydrazines, hydroxylamine, and nitrilotriacetic acid.

5.4 Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) are products of an incomplete combustion of organic materials, and can be found in some environmental matrices. Table 4 shows applications of ED methods to the analysis of aromatic hydrocarbons in environmental samples.

Either LC or HPLC is used for the analysis of PAHs; the analysis can be carried out by previous oxidation of the analytes with Ce(IV), and the final product (quinones) detected by reductive LC/ED at −0.4 V. The procedure is applied to tap water and motor oil.

The direct analysis of PAHs is carried out by oxidative HPLC/ED at +1.35 V. An SPE procedure is used for the preceding extraction/preconcentration step.

5.5 Polychlorinated Biphenyls

PCBs have been produced in many countries under different trade names, e.g. Aroclor®, Delor®, Sovtol®, or Kanerol®. The best known is Aroclor®, which is a mixture of chlorinated biphenyls characterized and numbered by the total percentage of chlorine in the mixture. The PCBs are toxic, the lethal oral dose (LD₅₀) is 2–10 g kg⁻¹ in mammals, and produce cancer. Because of their toxicity, the use of PCBs has been subject to some governmental regulations in many countries.

The determination of PCBs is of great environmental concern, because their release from industrial processes, combined with their insolubility in water and their resistance to biological degradation, has resulted in widespread contamination of water and soil. For several years PCBs have been recognized as ubiquitous environmental pollutants and these molecules are still presents in the environment, even though the production of PCBs has been banned. The conventional methods for quantifying PCBs are GC/MS or GC with electron capture detection. Table 5 shows applications of EC methods to the analysis of PCBs in environmental samples. Aromatic halogen-containing organic compounds can be reduced according to:

\[ RX + 2e^- + H^+ = RH + X^- \]

with reduction potentials being markedly affected by the nature and number of substituents in the aromatic ring. Although EC methods have not been widely applied for quantifying PCBs, some examples can be found, such as the following (all cited in): Kemula and Kreminska (1960) combined column chromatography and polarography to separate various isomers of dichlorodiphenyltrichloroethane (DDT) quantitatively; Colas et al. (1964) used silica gel to separate a mixture of two isomers of endosulfan, followed by polarography in a water–acetone mixture; Supin and Budnikov (1973) used the properties of α-benzene hexachloride at a slow DME to its determination at levels down to 60 µg L⁻¹ in pure solution; and Farwell et al. (1975) reported the use of interrupted-sweep voltammetric analysis to identify polychlorinated insecticides and other polychlorinated aromatics. However, this method requires at least 9 µg of relatively pure compound to obtain positive identification. Therefore it is not very helpful for the analysis of pesticide residues in the environment.

In 1984 Lam and Kopanica carried out an important EC application for the environmental analysis of PCBs. They determined TCB by adsorptive stripping voltammetry at a HMDE in the concentration range 0.004–1 mg L⁻¹. Preconcentration is achieved by adsorption at a potential of −0.40 V, and desorption at −1.10 V. This method was applied to the analysis of waste and natural waters with a relative standard deviation (RSD)

of below 5%. The cyclic voltammogram of TCB yielded a sharp cathodic peak, about four times higher than the anodic peak. TCB was accumulated on the surface of the HMDE in the more positive potential range and later it was stripped off at more negative potentials.

The current measured in the voltammetric determination of TCB depends on the pH of the supporting electrolyte. The optimum pH is in the range 6–7, where the TCB peak is well separated from hydrogen evolution. Because of the insolubility of TCB in water, voltammetric determination must be done in a buffer solution containing methanol. The dependence of the peak current on the TCB concentration was linear in the range $1 \times 10^{-8} – 1 \times 10^{-6}$ mol L$^{-1}$ TCB and the detection limit was found to be 1.5 µg L$^{-1}$.

Polarographically active metal ions such as Cu$^{2+}$, Pb$^{2+}$, Cd$^{2+}$, or Zn$^{2+}$ would not interfere if their concentration in the sample solution was up to 10 time greater than that of TCB; otherwise, masking with EDTA was necessary. However, surface-active compounds and organic compounds exhibiting adsorption properties similar to those of TCB may interfere; so, DDT can be determined under practically the same conditions as TCB. Thus it interferes with the TCB determination. The procedure was applied to different kinds of water and the results agreed very well with those obtained by the spectrophotometric measurements (Table 6).

The screening of PCBs in used mineral oils is carried out by a fully automated robotic method based on the dechlorination by sodium and a potentiometric measurement. The robot performs the weigh-in of the sample, adds the reagents, develops an LLE and measurement. The robot performs the weigh-in of the sample, adds the reagents, develops an LLE and measurement. The robot performs the weigh-in of the sample, adds the reagents, develops an LLE and measurement.

A current trend dealing with the EC analysis of PCBs is the development of EC immunosensors. Del Carlo and Mascini have developed an EIA with amperometric

in PBS at pH 7.4 after preparation for removal the adsorbed proteins and then thoroughly rinsed with PBS at pH 7.4, followed by air-drying. The dried PPY/antibody electrodes were stored covered at 4°C.

Antibody membrane electrodes are characterized by using cyclic voltammetry, chronoamperometry, and enzyme-linked immunosorbent assay (ELISA) protocols. The immunoreaction detection technique employed is referred to as a pulse-accelerated immunoassay technique (PAIT). The analytical signal was generated by applying a pulsed waveform between +0.60 and −0.60 V with a pulse frequency of 120 and 480 ms. The oscillating potential reversibly drove the antigen-antibody binding process. The current arising from this process was monitored in real time.

The sensor can be used for analyte detection in a static or flow injection (FI) mode by applying pulsed potentials between the sensor surface (or WE) and the reference electrode. The current obtained can be directly related to the rate of EC reactions occurring at the working (or sensing) electrode, which may be related partly to the concentration of the analyte in solution. Linear calibration curves of the peak heights (nA) versus concentration (µg L⁻¹) were obtained for various Aroclors®. The immunosensor exhibited a high selectivity for PCBs in the presence of potential interferences such as the chlorinated anisole, the benzenes, and the phenols. The highest cross-reactivity measured for chlorinated phenolic compounds relative to Aroclor® 1248 was less than 3%. Recoveries of spiked Aroclors® 1242 and 1254 from industrial effluent water, rolling mill, and seafood plant pretreated water ranged from 103 to 106%. The detection method may be applied to the continuous monitoring of effluent such as waste streams and groundwater.

5.6 Phenols

Phenolic compounds are released into the environment in a variety of ways, because they are used in many industrial processes. These include the manufacture of industrial products, such as plastics, pharmaceuticals, dyes and pesticides; agriculture also uses insecticides containing toxic nitrophenols.\(^{73−76}\)

The environmental concern of phenol pollution results from the high toxicity of many phenol derivatives to living organisms.\(^{77}\) Many phenols have a well-established reputation as toxic pollutants due to their toxicity and persistency in the environment. According to European Community legislation, the maximum admissible concentration of phenols in water for human consumption is 0.5 µg L⁻¹ for the total content and 0.1 µg L⁻¹ for individual compounds, excluding those natural phenols which do not react with chlorine; in bathing water the maximum admissible value is 5 µg L⁻¹.\(^{78,79}\) The analysis of phenols is very important in environmental programs due to their presence in natural and wastewaters. The USEPA lists eleven phenols as priority pollutants.\(^{80}\)

Different methods have been developed for the analysis of phenols. Traditional methods recommended for their determination are based on the measurement of an index of phenols using spectrophotometric methods based on 4-aminoantipyrine (4-AAP) or 2-nitrophenol;\(^{81,82}\) the result is expressed as total phenols, as individual phenols are not measured. These procedures have also been adapted to FIA, involving in-line concentration by solvent and sorbent extraction.\(^{73}\)

GC allows the speciation of the various substituted phenols after LLE. The USEPA Method 604 for phenols determination involves the serial extraction of an acidified sample with dichloromethane.\(^{83}\) The extract is dried and exchanged to 2-propanol, typically using Kuderna–Danish glassware, after that the phenols are analyzed by GC using a flame-ionisation detector. Alternatively, USEPA Method 625 for extractable base/neutral and acids can be used for phenols determination.\(^{84}\) The major limitation of these GC methods is the extraction procedure, where losses can occur during the steps of extraction, concentration, and solvent exchange. The extraction is also very laborious and intensive, so it requires specialized glassware as well as the use of chlorinated solvents. Table 5 shows applications of EC...
methods to the analysis of phenols in environmental samples.

EC methods have been applied to the determination of phenols, with or without a separation step. Differential pulse voltammetry\textsuperscript{(85,86)} and FI differential pulse voltammetry\textsuperscript{(87,88)} were used for the determination of several nitrophenols in spiked seawater and/or spiked river water employing modified carbon paste electrodes. The reduction waves of nitrophenols were used for quantification. Furthermore the interferent effects of several anionic species, cationic species, and other phenols were studied. The major interferences on individual nitrophenols were caused by some cationic species and other nitrophenols; chlorophenols, generally, did not interfere. The use of an adequate potential to accumulate certain nitrophenols on the WE can be used to avoid the effect of some interferents.\textsuperscript{(86)} The modified carbon paste electrodes can be also used for oxidations and the determination of several phenols in real water samples. However its sensitivity and selectivity could be improved if a preconcentration and/or separation step is applied.

A FI method using a dual EC detector was described for the analysis of total phenols in water and wastewater samples.\textsuperscript{(24)} The method relies on an in-line oxidative EC removal or an elimination of interferences at an upstream large surface area (coulometric) electrode combined with the oxidative detection of all phenols at an amperometric electrode. The method was compared with the standard colorimetric procedure based on 4-AAP. The results clearly indicate the increased accuracy of the FI method for the analysis of phenols in comparison with the data derived from the colorimetric procedure.

LC with an EC detector is widely used for the analysis of phenols. As with GC, LC also allows the speciation of various substituted phenols. The main advantage when using LC are that there is no requirement for precolumn derivatization and the need for sample pretreatment is minimal. So, LC and HPLC with ED are being widely applied to the measurement of phenols in environmental samples. Paterson et al.\textsuperscript{(89)} have developed a liquid chromatographic method for the determination of priority pollutant phenols at low microgram per liter levels in environmental waters. The phenols were separated using a Nova-Pak Phenyl column and optimized continuous (concave) gradient elution conditions, and subsequently they were detected using an EC detector equipped with a glassy carbon electrode, operated at +1.15 V (Figure 3). This approach resulted in minimal sample interferences and practical quantitation limits in the low microgram per liter range. The advantage this method offers over the established GC and GC/MS phenol methods is that no sample extraction is required, hence avoiding the losses which occur during the steps of extraction, concentration and solvent exchange required for the GC-based analyses. The method was evaluated following the determination of the 11 priority pollutant phenols in five ‘blind’ environmental water matrices. These samples were supplied (in duplicate) as part of a round-robin testing program involving nine laboratories. The samples, a saline oil refinery effluent, a spiked refinery effluent, a paper mill effluent, a spiked paper mill effluent and a spiked reagent grade water, were analyzed using either GC or LC methodology by the nine laboratories. The LC/ED sample chromatograms were virtually free of sample interferences. The LC/ED results and recoveries agreed with the results reached by the nine laboratories.

The HPLC technique also offers the possibility of separating high-polar and high-boiling phenols. The differences in their chromatographic behavior require gradient techniques to achieve good resolution in a short analysis time. ED can increase the sensitivity and selectivity for phenols, in comparison with other detection techniques, especially when an EC dual detector is used. Thus, Hagen et al. propose an isocratic HPLC with programmed flow-rate-variation and ED on a glassy carbon dual electrode in parallel mode for the determination of phenol, alkylphenols, hydroxyphenols,
and chlorophenols. The dual mode is used to increase selectivity. Whereas the WE, WE1, is held at +1.1 V, the other electrode, WE2, is held at +0.8 V. The potential of +1.1 V is necessary to reach the diffusion-controlled region of oxidation for all phenols. At a potential of +0.8 V only \( p \)-cresols (no \( o \)- and \( m \)-) are oxidizable. Therefore, an EC separation of the chromatographically nonresolved cresols is possible. The methods were successfully applied to the direct determination of phenols in samples of wastewater of a coal industry, and in samples of river water.

Table 7 shows the obtained results. The qualitative classifications were performed according to capacity factors \( (k) \) and peak-current ratios \( (I_{WE1}/I_{WE2}) \). Calibration curves served as the basis for quantification.

For the lowest phenols concentrations a preconcentration step is usually carried out. LC/electrochemistry was employed for the analysis of phenol traces in the range from 100 parts per trillion to 500 parts per million. Various sample preparation schemes were examined. The method was applied to wastewater from an oil refinery, municipal drinking water, and shale oil viscous materials. Direct injection was satisfactory for wastewater samples with phenol concentrations greater than 20 ppb. Municipal drinking water was analyzed for trace of phenols and chlorophenols in the 0.1–10 ppb range using trace enrichment. Regarding viscous shale oil materials, simple LLE into a base was enough to guarantee the measurement selectivity when coupled to LC/EC. Dual electrode detection provided additional information about peak identity.

Most reports about the analysis of phenols use SPE as the extraction technique. Ruana et al. have described a method for the determination of trace amounts of phenols in drinking and river water. They employ solid–liquid extraction of samples with laboratory-made microcolumns and LC with UV and ED to separate and identify the 11 EPA priority pollutant phenols. The EC detector was connected in series to the output of the UV detector and worked in the amperometric mode. The EC detector has a pretreatment function that allows the cleaning of the WE surface electrochemically. This function can occur before or in the middle of the analysis, avoiding premature fouling of the electrode. The detection limits obtained with prior concentration of the samples were 40–600 ng L\(^{-1}\), depending on the analyzed phenol.

The efficiency and the reproducibility of different solid-phase adsorbents such as C\(_{18}\) cartridges, C\(_{18}\) and poly(styrene–divinylbenzene) (PS-DVB) membrane extraction disks were evaluated for extractions of phenols from water at microgram per liter concentration levels. LC with coulometric detection was used for the analysis of the organic extracts. The limit of detection (LOD) for phenol and various chlorophenols in seawaters were estimated by the three different SPE protocols (Table 8). For C\(_{18}\) cartridges, LODs higher than those for SPE disks were obtained. The low breakthrough volume of phenol (20 mL) for C\(_{18}\) cartridges prevented the determination of this compound at concentrations lower than 0.25 \( \mu \)gL\(^{-1}\).

\( a \) Sample volume higher than breakthrough volume.

\( b \) An interferene prevented quantification.
For C_{18} and PS-DVB membrane extraction disks better LODs (between 0.01 and 0.04 µg/L) than for C_{38} cartridges were obtained because larger water volumes could be preconcentrated and, moreover, in a shorter period of time. The PS-DVB disks allowed the analysis of all phenols studied at the legislated level of 0.1 µg L^{-1}.

The PS-DVB membrane extraction disks were used as sorbents for the on-line solid phase extraction of 13 phenols (nitro and chlorophenols) in river and tap water by LC/ED. High water volumes, up to 250 mL, can be preconcentrated without loss of phenols (recoveries between 80% and 100%) except for the more polar ones. The LODs were studied in HPLC-grade water, tap water, and river water after preconcentrating different volumes of each one spiked by a low level concentration of phenols. In natural waters, detection limits were always higher than in HPLC-grade water. This fact was due to the matrix effects of natural water which especially affected to the compounds eluted with relatively short retention times; these limits were between 0.01 and 0.1 µg L^{-1} in tap water and between 0.1 and 1.0 µg L^{-1} in river water. The method was applied to two river water samples (both crossing industrial zones) employing the standard addition method for quantitative analysis.

A high-sensitivity method for the determination of polar phenolic compounds in water samples was developed. Water samples were preconcentrated using on-line SPE with a styrene–divinylbenzene sorbent. They were analysed by LC/dual coulometric detection, with the first electrode set at low potential for sample clean-up and the second electrode being used for analytical purposes. The method was applied to spiked groundwaters. Detection limits at part per trillion level were attained.

A reversed-phase HPLC procedure with gradient elution and ED, coupled with a preconcentration step by SPE using a derivated PS-DVB, is described for the determination of various phenolic compounds. The successful method was used to determine phenols in seawater samples collected from a contaminated coastal area by wastewaters from an iron works, a steel factory, and a refinery; although the matrix was complex and contaminated by aliphatic and polycyclic aromatic hydrocarbons, the determination of phenolic compounds was simple and not affected by interferences.

A present trend for the analysis of phenols in environmental samples is the use of biosensors. The catalytic properties of several enzymes have been exploited for the construction of biosensors with narrow or broad selectivity for phenolic compounds. The sensors can be applied to the determination of phenols in real surface waters. Analyte-specific biosensors (type I) can be constructed by choosing a specific enzyme that catalyzes the conversion of a specific analyte structure, leading to a narrow substrate selectivity. A group-specific biosensor (type II), leading to a broader substrate selectivity, can be constructed by choosing an enzyme that catalyzes a whole group of related analytes of similar structure or several analyte-specific enzymes that are co-immobilized in the same biosensor. Both types of biosensors have been developed on the basis of phenol oxidases (tyrosinases, laccases) and peroxidases, using different electrode material, flow systems, and sample pretreatment techniques.

Although oxidases and peroxidases have different enzymatic mechanisms, their action in amperometric biosensors for detection of phenolic compounds can be illustrated with a similar reaction sequence at an enzyme-modified electrode (Figure 4).

Amperometric electrodes for the determination of phenolic compounds are essentially two types:

- Surface-modified solid electrodes, where the enzyme is physically adsorbed, covalently immobilized or membrane retained.
- Bulk-modified composite electrodes, where the enzyme is incorporated in the bulk of the electrode material.

![Figure 4](image)

**Figure 4** Operational mechanism of enzyme-modified electrodes for the determination of phenolic compounds. E_{red} and E_{ox} are the reduced and oxidized forms of the enzyme, respectively; Ph, Ph*, and Q are the phenolic molecule, its phenoxyradical and its quinone form, respectively. (Reproduced by permission of Elsevier Science from ref. 49.)

![Figure 5](image)

**Figure 5** Optimal potential range for the operation of amperometric biosensors. (Reproduced by permission of ref. 92.)
The optimal potential range for the development of amperometric phenolic biosensors lies between −0.2 and 0 V (Figure 5). In this region the background current switches signs, leading to low noise and background currents, and thereby enabling the detection of low analyte concentrations. Outside this region several interference reactions can occur; special care should be taken with environmental water samples that contain different amounts of electrochemically active matrix compounds, such as humic substances.

For use with real water samples, biosensors are generally incorporated into fully integrated analytical flow systems, whose choice is often determined by the concentration of phenolic compounds in the sample and the complexity of the sample matrix. At levels of 1 µg L⁻¹ and below, direct measurements with any type of biosensor are practically impossible because of the lack of sensitivity (except for the best enzyme substrates). A sample-enrichment step is required to extract the phenolic compounds from larger sample volumes, which is not usually a limiting factor for environmental applications. Solute extraction can be performed off-line on a membrane extraction disk or a disposable extraction cartridge, where the enriched sample is injected into a flow system. On-line systems are designed to eliminate tedious manual sample-handling procedures and contamination. SPE is an efficient sample handling technique that allows phenols to be monitored in highly complex samples at higher level, such as industrial wastewaters and effluents.

Biosensor applications to the determination of phenols in real samples are not still very abundant. An amperometric biosensor based on the phenol oxidase tyrosinase immobilized on solid graphite electrodes as a selective and sensitive detector in column liquid chromatography (CLC), with SPE as sample handling step, was used for the determination of phenolic compounds in spiked wastewater samples obtained from a pulp-producing plant in the south of Sweden. Peroxidase-modified electrodes as amperometric detectors in FI systems were employed to determine phenols in humic-containing surface water from the Ebro river in Spain. A remote EC biosensor for field monitoring of phenolic compounds was proposed. The sensor is based on a tyrosinase enzyme electrode connected to a voltamnograph via an environmentally sealed connector and a 50 ft shielded cable. The submersible probe offers highly selective measurements of micromolar concentrations of phenolic substrates in untreated river and groundwater samples.

5.7 Pesticides

Pesticides are materials created to destroy or control any pest. The term ‘pesticides’ may also refer to substances used as plant-growth regulators, defoliants, agents for preventing the premature fall of fruit, and chemicals applied to crops either before or after the harvest to inhibit deterioration during storage or transportation. The term pesticide includes the diverse range of substances variously classified as insecticides, fungicides, molluscsides, bactericides, rodenticides, fumigants, and herbicides.

Pesticides are highly toxic compounds. The health hazards arising from their use include bone marrow disorders, carcinogenicity, infertility, cytogenic effects, immunological and respiratory problems, and some of them (organophosphates) are powerful inhibitors of enzymes involved in nerve functions. The organochlorine insecticides (such as DDT, aldrin, and lindane) used in the past have been progressively replaced with organophosphates and carbamates, which have low environmental persistence though they are still highly toxic compounds. For these reasons, the 1989 European Community Water Act states that the maximum admissible concentration of all pesticides in drinking water should be below 0.5 µg L⁻¹ and the individual pesticide concentration below 0.1 µg L⁻¹.

A number of methods can be used for the determination of the pesticide content in environmental samples. Most of the early methods used were based on spectrophotometric procedures or the determination of total phosphorus. These methods were slowly superseded by GC which is undoubtedly the most common and, when coupled to FTIR or MS, has the ability to fingerprint pesticides. However, because of the thermal lability and low volatility of some pesticides, cold methods such as LC and EC methods are increasingly used for the determination of these compounds. Table 9 shows the application of EC methods to the analysis of pesticides in environmental samples.

The direct determination of pesticides in water without separation/preconcentration techniques has rarely been carried out; the EC reduction of 1,2-dibromoethane (EDB) in aqueous solution has been studied with direct current, normal pulse and reverse pulse polarography, voltammetry, and coulometry. The reduction mechanism involves a slow two-electron transfer with a fast displacement of bromide leading to the formation of ethene. The EDB can be determined directly from the limiting reduction current or indirectly from the limiting current for the anodic oxidation of mercury in the presence of the reduction product, bromide.

Adsorptive stripping differential pulse voltammetry was employed for the determination of the organophosphorus pesticide azinphos-methyl (Gution). Accumulation is achieved by the adsorption of the compound on an HMDE. The method was applied to the determination of Guthion in river water. The samples were collected...

CSV, cathodic stripping voltammetry. Kel-F®, registered 7 M of 3 M Co.
from a river near where a factory that produces the insecticide is located. As no residues of Guthion were found, the procedure was applied to spiked river water. The determination limit was 1.5 ng mL$^{-1}$.

CSV was used for the determination of the herbicide paraquat (1,10-dimethyl-4,4′-bipyridylum ion) on a carbon paste electrode modified with Amberlite® XAD-2 resin. The procedure exhibits good linearity for concentrations of paraquat lower than 1.08 mg mL$^{-1}$ with a detection limit of 0.10 g mL$^{-1}$. The method was applied to river water samples, but the presence of paraquat was not detected. To establish possible matrix effects, samples of river water were spiked with paraquat then analyzed with the proposed method, obtaining recoveries of 104% with a precision of 6%.

A voltammetric procedure for the determination of the pesticide Ioxynil (4-hydroxy-3,5-diiodobenzonitrile) by adsorptive stripping using a C$_{18}$ carbon paste-modified electrode was carried out and applied to determination of the compound in drinking water; however, the sensitivity was not enough to control concentrations of pesticides according to the national regulations. Also an anodic voltammetric assay using a silica modified carbon paste electrode for the herbicide Metamitron (4-amino-3-methyl-6-phenyl-1,2,4-triazin-5-(4H)-one) was proposed to determine the compound in natural water with a detection limit of 75 ng L$^{-1}$.

LC with ED is one of the most-used techniques for the determination of pesticides and has been applied to the determination of carbamate pesticides spiked into a river water matrix using a series of Kelgraf microarray electrodes. The Kelgraf electrode effectively discriminates between oxidation reactions limited by the rate of mass transport and reactions (including solvent oxidation) limited by the rate of electron transfer or other surface processes, affording improved detection limits at high applied potentials. Subnanogram detection limits are obtained with minimal sample clean-up or pretreatment. The HPLC technique with coulometric electrode array detection and with amperometric detection was also employed for determination of amitrole (3-amino-1,2,4-triazole) in spiked drinking and groundwater. A sensitive and simple method for the simultaneous evaluation of phenol and 26 substituted phenols and phenylurea herbicides was developed using HPLC with multielectrode ED. After extraction from the samples on solid-phase cartridges, the compounds were separated on a reversed phase column by using a combined gradient of organic modifier and counter-ion. The identification of the compounds was based on the retention time comparison with authentic standards. The detection limits for the 27 compounds studied was found to be much lower (5 × 10$^{-4}$ g L$^{-1}$ for the least-sensitive compound, the herbicide Linurom) than that indicated by the European Community. The method was applied to the determination of three phenylurea herbicides and four phenols in three different samples of water, namely tap water from an aqueduct, water from a spring at 1,600 m above sea level, and commercial mineral water.

The monitoring of trace levels of phenylurea and chlorotriazine herbicides and their metabolites was performed on river, estuarine and coastal seawater by off-line (n-octadecyl silica, C$_{18}$) and on-line (styrene–divinylbenzene copolymer-based) preconcentration techniques using reversed phase chromatography and UV and ED. It was shown that the off-line and on-line technologies fit monitoring of trace-level phenylurea and triazine analysis (detection limits 10–50 ng L$^{-1}$) in fresh water as well as seawater and in natural water with high dissolved organic carbon content.

Other flow systems, such as FIA, have been combined with ED for the environmental analysis of pesticides. Thus an ion selective electrode (ISE) has been developed for the herbicide paraquat based on a membrane of octamethylocyclotetrasiloxane and highly lipophilic PVC-based components (i.e. plasticizer and anionic sites), fixed on the surface of platinum wire and subsequently used as a flow-through potentiometric detector. Analysis of 0.01 mM paraquat dichloride in the background of well, river and lake waters when performed in the FIA mode gave excellent recoveries. A technique for the rapid and sensitive FI monitoring and analysis of mixtures of the triazine herbicides simazine, atrazine, and propazine using filter-supported bilayer lipid membranes was also described.

EC biosensors and immunosensors are being developed for the environmental analysis of pesticides. In general, the pesticides are not the substrates of enzymes but acts as specific inhibitors of their activity. Consequently their detection is not generally based on the enzymatic catalysis of the pesticide but on the inhibiting capacity of a specific enzyme activity.

Cholinesterases, inhibited by organophosphorus and carbamate pesticides, are practically the only enzymes used in pesticide potentiometric biosensors. The prevalence of the use of biosensors for organophosphorus and carbamate biosensors may be related to the fact that in 1994 they accounted for more than 57% of the total world insecticide market. Moreover, activity of cholinesterase enzymes can be easily monitored by EC methods. The two types of potentiometric transducer mainly employed are the ion-selective electrode (the glass pH electrode), and the ISFET – a semiconductor that monitors pH change. Other transducers, such as

light-addressable potentiometric sensor (LAPS), are less used.

With amperometric biosensors, choline oxidase is employed in addition to the esterases. This allows the indirect monitoring of choline by measurement of the consumption of oxygen or the production of hydrogen peroxide. Furthermore, the direct anodic measurement of choline or thiocholine using a biosensor either with or without a suitable mediator of the electron transfer, can be used.

The sensitivity reached with cholinesterase sensors depends on the type of cholinesterase and the source. Table 10 shows detection limits reached for amperometric and potentiometric sensors applied to the determination of several carbamate and organophosphorus insecticides; lower detection limits are always obtained for amperometric detection.

EIA technologies are a rapidly growing tool for pesticide measurement, and several EIA test kits are commercially available. These methods are indirect techniques, and detection of molecular interactions needs the use of a label such as an enzyme, fluorophore, or radioactive isotope. Using these kits it is possible to detect 0.02–2 µg L⁻¹ in water, depending on the pesticide and the antibodies involved. The disadvantages of these commercial kits include slow equilibration time and irreversible binding which prevents re-use or continuous application.

The wide application of disposable strip tests in clinical analysis and environmental analysis for field control suggests that EC biosensor and immunosensors could also find a wide acceptance for the determination and monitoring of pesticides. Such sensors could serve as an alternative to chromatographic methods which, although more versatile in providing information about numerous species from one run, are much more expensive, require well-trained personnel, and cannot be used readily in the field. However, there are practical obstacles to be overcome before EC biosensors and immunosensors will make a significant impact in environmental applications. In particular, it is necessary to improve the transduction mechanisms and to combine such improvements with the choice of biological transduction sequences and materials, and EC science.

5.8 Surfactants

Surfactants are an important source of pollution due to their extensive industrial and domestic use. Reviews on the determination of ionic and nonionic surfactants are provided, with application to surface water and wastewater. Table 11 provides information on the determination of surfactants and organometallics by EC methods.

Particular attention is given to indirect tensammetric techniques useful in the analysis of non-ionic surfactants. EC techniques applied for the determination of surfactants have been reviewed. Table 11 shows applications of EC methods to the analysis of surfactants in environmental samples.

Potentiometric electrodes selective for ionic surfactants have been developed. These electrodes are ISEs with a liquid membrane containing a complex of an ionic surfactant that is insoluble in water and behaves as a liquid ion exchanger. Several ISFET devices have been developed to detect different ionic surfactants in environmental water samples, such as river, lake, and seawater.

A membrane electrode based on poly(ethylene oxide) for determination by potentiometric titration of nonionic surfactants has been described as an alternative method for determination in wastewater.

Primary biodegradation of nonionic surfactants can be tested with an indirect tensammetric procedure. These compounds are also determined in river water by the same technique; the method for nonionic surfactants adsorbed on particles of river water combined the bismuth-active substances method with the indirect tensammetric method. Detection limits in the range 3–8 mg L\(^{-1}\) are reported.

Metabolic products from the biodegradation of surfactants are also the object of analysis. Poly(ethylene glycols) is one of the major products of the biodegradation of nonionic surfactants and their determination is of great interest for control of the aquatic environment. A process of extraction must be carried out in order to separate poly(ethylene glycols) and nonionic surfactants. Applications to river water are reported.

Polarography has been applied to the determination of nonionic surfactants and linear alkylbenzene sulfonates. Nonionic surfactants are transformed into complexes with molybdophosphoric acid prior to their polarographic determination; applications to surface water and wastewater are reported. Linear alkylbenzene sulfonates are anionic surfactants commonly used in the detergent industry; for these compounds, a previous nitration step with fuming nitric acid is proposed. Applications to sewage are reported.

5.9 Organometallics

A variety of organoarsenic compounds are found in the environment as the result of industrial activity. EC determinations of organic arsenic compounds offer the possibility of differentiating between different oxidation states of arsenic compounds. New EC developments include sensors for the determination of gaseous arsines and the use of capillary electrophoresis for a prior separation step.

Organotin compounds have been extensively used as wood preservatives, stabilizers for PVC plastics, fungicides and antifouling paint additives. Organotin compounds have different degrees of toxicity depending on the nature and number of the alkyl groups bonded to the tin atom. Alkyltin compounds are more toxic than the aryl compounds, and the trisubstituted derivatives more toxic than the di- or tetrasubstituted derivatives. Analytical methods for organotins in the environment can be found in a review. Most analytical methods applied to the analysis of environmental samples involve a derivatization step to transform organotin compounds into volatile hydrophobic analytes and their analysis by GC. However, methods based on LC or supercritical fluid chromatography are being developed to avoid some problems related to this procedure. For example, a differential pulse anodic stripping voltammetry method at a binuclear ruthenium complex coated glassy carbon electrode has been described for organotins. Alternating current polarography is used for the determination of tributyltin in seawater; samples were passed through a cation exchanger, and the eluate extracted with dichloromethane.

Environmental toxicity of mercury compounds depends on their different chemical form and oxidation states. Symmetric organomercurials are inactive, whereas alkyl and aryl mercury have a high toxic activity; methylmercury leads to extremely toxic effects on biota and humans. Thus, it is important to know both the concentration of mercury compounds and their chemical forms and oxidation states. River water samples have been analyzed by reversed-phase HPLC with amperometric and coulometric detection, and the contents of methyl-, ethyl-, and phenylmercury have been determined. The procedure includes the complexation reaction of mercury species with pyrrolidineethio carbamate, and SPE of the complexes, prior to their introduction into the chromatographic system. A carbon paste or glassy carbon electrode is used for amperometric detection, and a glassy carbon electrode for coulometric detection. Limits of detection lower than 0.2 mg L\(^{-1}\) were reached in all cases; the best results are always obtained with coulometric detection. An EC enzyme probe has been also developed for the determination of methylmercury and ethylmercury.

Organolead compounds appear in the environment due to their use as an additive in gasoline. These compounds are emitted from motor vehicles, and the emissions include tetraalkyllead compounds and ionic alkylleads. Ionic alkyllead compounds are determined in natural waters by differential pulse anodic stripping voltammetry by means of the reextraction of the compounds from...
carbamate complexes to an acid aqueous solution.\textsuperscript{136,135} Table 11 shows the applications of EC methods to the analysis of organometallics in environmental samples.

### 5.10 Miscellaneous Compounds

Ethylenethiourea is a environmental metabolite of some fungicides, high contents of which cause thyroid enlargement and cancer. The low volatility of ethylenethiourea needs derivatization for GC analysis, and the low UV absorbance maximum (232 nm) makes LC with UV detection susceptible to the interferences found in typical environmental samples. Pulsed amperometric detection (PAD) is used for the analysis of thiourea derivatives. The potential–time waveform is a \(0.6\ V/1.2\ V/-0.6\ V/0.6\ V\) sequence.\textsuperscript{136}

9,10-Anthraquinone is of great interest in connection with production of dyestuffs and pharmaceuticals. The determination is carried out by differential pulse voltammetry. The origin of the water sample dictates the procedures used for sample treatment.\textsuperscript{37}

A procedure for the determination of total phthalate esters as phthalic acid in environmental samples is based on differential pulse voltammetry. The phthalate esters are used as plasticizers and, due to the increasing use of plastics, these esters have become widely distributed and are important organic pollutants. The method has been successfully applied to determine total phthalate esters in wastewater with a previous extraction procedure.\textsuperscript{38}

Applications of EC methods to the analysis of miscellaneous compounds in environmental samples described above are shown in Table 12.

### 6 COMPARISON WITH OTHER TECHNIQUES

Numerous analytical techniques can be employed for the determination of organic pollutants in environmental water and wastewater samples. Among them EC ones play an important role.

In general terms it can be said that the determination of the smallest amounts of substances is the domain of radiochemical methods, especially of activation analysis and tracer techniques, which can attain detection limits, in optimal cases, of the order of \(10^{-11}\) g. Among the physicochemical analytical methods, MS, MS/GC or MS/LC, UV fluorescence, emission spectral analyses reach detection limits from the former amount to around \(10^{-12}\) g.

In the range from about \(10^{-9} - 10^{-10}\) g, or in the concentration range \(10^{-6} - 10^{-10}\) M, a number of physicochemical methods can be used, starting with spectrophotometric, atomic-absorption spectroscopy and fluorescence, through kinetic and catalytic methods, to EC methods. With EC stripping detection limits up \(10^{-12}\) M can be attained.

The most frequent comparison carried out in the environmental analysis of water samples and involving electroanalytical techniques, is between UV detection and the ED using chromatographic techniques. Thus, comparative studies between both types of detection for the determination by LC of priority phenols in river waters\textsuperscript{141} and in drinking waters and river waters\textsuperscript{91} have been carried out. In order to compare the performance of LC/UV and LC/EC, the EC detector was connected in series to the output of the UV detector in amperometric mode.

ED of phenolics requires applied potentials of around 1 V, which can cause other matrix components to be oxidized, thus increasing the background current. Apart from that, the use of high applied potentials can cause electropolymerization of phenolics at the electrode surface, with a decline in signal response with time. A high amount of humic substances in water samples can also cause a reduction in the signal response. Nevertheless, the electrode surface can generally be cleaned by applying a

| Table 12 | Environmental analysis of miscellaneous compounds by EC methods |
|---|---|---|---|---|
| Analyte | Sample | Detection limit | Comments about the method | Ref. |
| Miscellaneous compounds (Ethylenethiourea) | groundwater | 5 µg L\(^{-1}\) | PAD at a gold electrode | 136 |
| (9,10-Anthraquinone) | natural water | 2 mg L\(^{-1}\) | DPP | 37 |
| (Motor oils) (Phthalate esters) | polluted water | | adsorptive stripping voltammetry at a HMDE | 137 |
| (Peroxides) | wastewater | | DPP | 38 |
| | river, groundwater | | peroxidase-based biosensor; submersible bioprobe for continuous monitoring | 138 |
| | wastewater | | polarographic determination | 139 |
| | drinking water | | reversed-phase HPLC with amperometric detection | 140 |
cycle of alternating negative and positive potentials, or by the use of the PAD.

However, not all the solvents used in LC can be used with an EC detector, as some can attack certain internal parts of the detector. Working with gradients in ED causes both the conductivity of the mobile phase and the potential of the solid state reference electrode to be slightly changed during elution of the analytes. This makes the real applied potential for every analyte dependent on their retention times. However, by recording the calibration graph always under the same experimental conditions the quantification is not affected.

By comparing the chromatographic profiles obtained from the two detectors when processing 50–100 mL of river water sample spiked with phenolics at the 1 µg L\(^{-1}\) level, it can be seen that interferences make the identification and quantification of analytes when using UV detection difficult. This is especially true for the humic substances which can be found in the river water, which affect the beginning of the chromatogram, thus hampering the monitoring of low-retention-time analytes such as phenol. A cleaner profile was obtained when working with an EC detector, which allows identification and quantification of all the target compounds. Nevertheless for very high contents of humic substances the electrode response may be altered and it is found appropriate to diminish the sample volume.

In Table 13 the detection limits obtained in groundwater with both types of detectors are shown. It can be observed that the sensitivity of ED is around 100 times better than for UV detection, for all the phenols except the nitrophenols, because the working potential used (+1 V) was not optimum for determining nitrophenols. It can be concluded that the use of both type of electrodes in LC can be the most appropriate procedure for phenols determination at the required environmental levels.

A FI method using a dual EC detector for the analysis of total phenols in water and wastewater samples has been proposed as an alternative to the standard colorimetric procedure.\(^{(24)}\) It is verified that whereas the 4-AAP colorimetric method for the determination of total phenols is unreliable when the water samples contain appreciable levels of certain substituted phenols, the FI/EC procedure significantly improves the accuracy of the determination of total phenols when there are substituted phenols.

The comparison of UV and ED in HPLC for the analysis of some organophosphorus pesticides\(^{(142)}\) and some nitrogen-containing pesticides\(^{(143)}\) has also been performed. In general, ED is more sensitive and, particularly for the nitrogen-containing compounds studied, the EC method was found to be 20–240 times more sensitive than the UV method. Furthermore, the reproducibility of the EC method is also better than for UV.

ED in HPLC is also more sensitive than UV detection for the analysis of residues of explosives in water samples.\(^{(13)}\) Moreover, ED shows other advantages, as it allows the selective detection of nitrophenols in the presence of some nitramines and some nitrobenzoic acids, and it shows several chromatographic peaks undetectable with the UV detector (Figure 6).

Figure 6 Chromatograms of the neutral basic/fraction of a groundwater from Elsnig: (a) UV detection (254 nm); (b) ED (+1.2 V). (Reproduced by permission of Elsevier Science from ref. 13.)

An off-column amperometric cell was also used for monitoring nitroaromatic explosives separated by electrokinetic capillary electrophoresis. The amperometric detector measured several explosives in extracts prepared from contaminated soils and in groundwater samples successfully. Such a detection system offered a 10-fold detection limit improvement over UV measurement for most of the explosives tested.

ORGANIC ANALYSIS IN ENVIRONMENTAL SAMPLES BY ELECTROCHEMICAL METHODS

55. US Environmental Protection Agency, *EPA method 605*

Many organometallic species exist in the environment and these may range from being completely nontoxic, e.g. the arsenic compound arsenobetaine, to exceptionally toxic, e.g. methyl mercury. Compounds of intermediate toxicity, such as the arsenic species dimethylarsinic acid and monomethylarsonic acid also exist. Determining the chemical form or speciation of samples is vital in environmental impact assessment as it affects bioavailability and mobility in the environment. Speciation analysis usually comprises a number of analytical steps. Sampling and sample storage are critical and must be performed in such a way that ensures a representative sample whilst preventing changes in speciation or losses of some of the more labile species. Sample preparation normally requires the extraction of the species of interest from the sample materials. This may be achieved in a number of ways that are discussed in detail in the relevant section. Sample cleanup and derivatization methods that may be required if gas chromatographic methods of analysis are to be used are also discussed. The actual sample analysis stage is discussed in detail and this concentrates mainly upon different chromatographic techniques coupled with assorted atomic spectrometric methods of detection. This is because these so-called ‘coupled’ techniques are used for the majority of speciation analyses. Other nonchromatographic methods of sample introduction to atomic spectrometric detection, such as hydride generation (HG), are also discussed together with techniques including more conventional detectors for the chromatographic techniques (such as ultraviolet (UV)/visible, fluorescence, flame ionization detectors (FIDs), electrochemical detectors, etc.), electrochemical methods, nuclear magnetic resonance (NMR) and infrared (IR) spectroscopy. In addition to obtaining quantitative data, techniques such as NMR and IR spectroscopy may be used to obtain structural information on individual species.

Method validation is as important for speciation analysis as it is for any other analysis. This may be achieved using mass balance data, the analysis of certified reference materials (CRMs) or using completely independent analysis techniques. The text gives an overview of all stages of the analysis, highlighting potential pitfalls and areas of uncertainty.

1 INTRODUCTION

Since the late 1980s, there has been increasing interest in determining not only “total” concentrations of analytes, but also the concentrations of individual forms of the element. The determination of the different forms of elements is known as speciation analysis. The interest in this area stems from increased knowledge of the chemistry of the environment and the way in which anthropogenic inputs can affect it. Several different elements can form a number of species. These forms can be of different oxidation states but many have an organic moiety associated with them. These organometallic compounds usually have both different biogeochemical cycles and different toxicity when compared with the inorganic forms and hence they are of interest to food scientists, environmental scientists and ecologists. In general, it can be said for some elements, e.g. lead and mercury, that the organometallic forms of elements are more toxic than the inorganic forms. Obvious exceptions to this general rule are arsenic and selenium. Inorganic arsenic is a well-known poison, but many of the organic forms, e.g. arsenobetaine and arsenocholine, are generally regarded as being nontoxic. This is because these molecules are extremely stable and resist enzymatic or oxidative attack even by reagents such as concentrated nitric acid. The
potentially dangerous arsenic is therefore effectively immobilized. Therefore if a substantial amount of seafood is consumed, the arsenobetaine that will be present, often at high concentration, will not be attacked by the enzymes or stomach acid of the body and will be excreted in the normal way without any adverse effects.

Organic forms of many elements are regarded as being more toxic than inorganic forms. This is because the organic forms are more readily absorbed through the gut lining and because they pass through the blood–brain barrier. The latter is especially true for methyl mercury. This compound attacks the blood–brain barrier and disrupts the metabolism of the nervous system. In addition, it can cross the placenta more easily and it is this property that led to the Minamata poisoning case in Japan. In this incident a factory released mercury into the sea; this mercury underwent biomethylation, thereby contaminating local fish stocks. Ingestion of the fish by expectant women led to 22 infants being born with serious brain damage whilst the mothers showed only marginal symptoms of mercury poisoning.

There are a number of natural phenomena that effect the speciation of elements. Many organic compounds are destroyed by the action of light (photolysis), e.g. organotin compounds and arsenobetaine. There are a number of bacteria capable of biomethylation and there are other bacteria that demethylate metals. Elements whose speciation is affected by these bacteria include mercury, tin and arsenic. It is also known that some moulds are capable of methylating inorganic arsenic. Methylated is also hypothesized as the method by which vertebrates detoxify inorganic arsenic.

Anthropogenic inputs to the environment such as tributyl tin (TBT) from antifouling paints or triphenyl tin from fungicides are known to cause deleterious effects to shellfish (e.g. imposex and shell thickening). In the environment, these species will slowly be detoxified by a stepwise dealkylation, forming dibutyl tin, followed by monobutyl tin and finally inorganic tin. The same process also occurs for the phenyl tins, which are dearylated in a stepwise manner. Once in the environment, these tin species may also be methylated by bacteria. Hence, a plethora of different species may be formed.

From this brief overview it is obvious that a very large number of different species for many elements exist in the environment. To determine the overall toxicity of a sample, or to gauge the extent to which a breakdown process has occurred, it is necessary to perform speciation analysis. There have been a very large number of methods employed, of which the relative advantages, disadvantages and pitfalls of each are discussed in later sections. A recent publication has summarized these, but has not gone into specific problems. Other books that have summarized speciation include one by Quevauviller. This book has several chapters on the speciation of individual elements and also a chapter devoted to speciation analysis of environmental samples. In addition, possible sources of error and the preparation of CRMs to validate analytical methods are also discussed. The latter subject was the main focus of a previous book. An overview of analytical methods used for elemental speciation has also been made. Numerous other reviews have concentrated on the speciation analysis of certain elements. Examples include reviews on arsenic, lead, tin, mercury and selenium.

2 SAMPLE COLLECTION AND STORAGE

As for normal analytical chemistry, the sampling and storage strategies are of utmost importance. If performed incorrectly, all subsequent steps in the analysis are pointless. A book produced by the Royal Society of Chemistry gives invaluable information on sample collection and storage. It is important that the correct sample is taken. For instance, if a sediment is to be analyzed, it should be taken whilst ensuring that weed, slimes, twigs and leaves are not sampled simultaneously. Care should be taken to store an anoxic sediment under nitrogen and to avoid undue temperature increases. Another good overview on sampling strategies and sample storage has also been produced.

Different sampling methodologies are required for different sample types. Sample homogeneity is easily ensured for gaseous and liquid samples, but solids may cause problems. Contamination may be a problem for all three sample types, but can be especially bad for liquid or gaseous samples. For water samples, the type of collection vessel used will depend on the depth from which the water is to be sampled. Clean plastic bottles may be used to collect samples from shallow water or close to the surface. If sampling from deeper water is required, GoFlo™ samplers or other specialized sample collection devices may be necessary. The material from which the container used to collect the sample is made will also depend on the analyte. Mercury vapor is known to pass through low-density plastics and therefore collection and storage in a plastic bottle should be avoided. Similarly, some organotin compounds are used as plasticizers and therefore sample collection and storage in plastic containers may lead to contamination. Under circumstances such as these, it may be better to collect and store samples in glass bottles. It has become popular to collect the sample by isolating the species of interest on a microcolumn of adsorption media. Once the sample has been collected, the microcolumns can be returned to the laboratory and inserted into a flow injection
ORGANOMETALLIC COMPOUND ANALYSIS IN ENVIRONMENTAL SAMPLES

3

Sample preservation is not as straightforward as in “total” metal determinations. Under normal circumstances, water samples are acidified to prevent adsorption of metals to glass containers. The addition of acid may alter the speciation for many analytes, e.g. change the oxidation state or perhaps demethylate some species. Similarly, potassium dichromate is often added to samples to stabilize mercury. This may also lead to species oxidation. The effect of the preserving agent on the species of interest should always be determined using pure standards prior to sample collection. If the speciation is found to be unaltered, it is permissible to use the preservation agent.

Preservation of solid matrices is relatively simple. Often, the sample must be dried although care must be taken to ensure that this does not lead to a change in speciation or loss of volatile species. Freeze drying is often preferred to oven drying, as the risk of species loss is less. Drying of the material prevents the growth of mould on many biological samples (which may change the speciation). Some laboratories may irradiate the samples to prevent the growth of mould. This should again be viewed with suspicion as irradiating samples may also lead to species conversion (e.g. dealkylation of organotin species). It is worth emphasizing again that the effects of any process performed on, or reagent added to, the sample should first be checked using pure standards of the species of interest. Only then is it possible to deduce whether or not it is a valid step in the analytical process.

Sample storage can also lead to analyte losses, contamination or speciation change. As described in the introduction, most organotin and some arsenic species are light sensitive. It is therefore important that they be kept in the dark. This may be achieved by storage in darkened glass bottles or by wrapping clear glass containers with aluminum foil. Any sample degradation may be slowed by freezing the sample, or by storing it below room temperature (e.g. at 4 °C in a refrigerator). It must be noted that freeze-dried samples will slowly absorb water and therefore if they are analyzed at a later date, a further drying stage (on a separate subsample to that being analyzed) must be performed so that an accurate moisture content correction can be applied. As the moisture content increases, the likelihood of bacterial decomposition increases and hence refrigeration becomes even more important. Storage of “anoxic” sediments may be particularly problematic.

3 SAMPLE PREPARATION

3.1 Aim of Sample Preparation

The aim of sample preparation is to obtain the species of interest in a form and at a concentration in which
it may most easily be determined using the techniques at the disposal of the analyst. Sample preparation techniques may consist of a number of different analytical steps, all of which have some sources of error or uncertainty associated with them. An overview of the pitfalls in speciation analysis has been produced by Rauret and Rubio.\(^{(17)}\) The amount of sample preparation required depends on several factors including the matrix type, the species of interest and the method of analysis. Gaseous samples normally require least sample preparation because often they may be introduced directly to an instrumental technique such as gas chromatography (GC). Liquid samples may require preconcentration so that the concentration of the species is increased to a level where determination is facilitated. This may be achieved in a number of ways, including solvent extraction and enrichment using solid-phase extraction media. Another sample preparation step that may be necessary is filtration to remove unwanted solids, e.g. twigs or suspended particulates. This may also pose problems, because some species, e.g. TBT, are known to adsorb very strongly to particulate material. If the analyst filters the sample, the majority of TBT will be removed and hence erroneously low estimations of its concentration will be made. Solid matrices require more attention. The species must be extracted from the solid material in a quantitative (or at least representative) manner, whilst ensuring that no change to the speciation has occurred. This is often the most difficult part of the analysis, with numerous different methodologies having been developed.

Once isolated from the matrix, the species may sometimes be determined directly, but depending on the method of analysis further sample manipulation may be required. GC requires the analytes to be volatile. Therefore if the species are relatively involatile, they must be converted into a form that can be vaporized more easily. This requires a derivatization step.

The extraction, derivatization and cleanup steps will be described in more detail below. A brief overview of extraction procedures for speciation analysis of environmental samples has been made by Morabito.\(^{(18)}\) This paper briefly discusses the most common extraction techniques for Pb, Sn, Hg, Cr, As, Se and Sb in liquid and solid samples.

### 3.2 Extraction of Species from Liquid Samples

This process is one of the easier steps in speciation analysis. Simple liquid–liquid extractions have proved popular because they afford large preconcentration factors (in excess of 100), whilst separating the species of interest from the bulk of the matrix (and hence potential interferences). Other species require derivatization followed by extraction into a suitable solvent prior to analysis.

Solid-phase extraction is becoming far more popular, as it is readily automated. An overview of solid-phase extraction applied to metal speciation has been published by Urasa et al.\(^{(19)}\) There are a variety of techniques that may be used, including assorted resin-based media, extraction discs, polyurethane foam and, more innovatively, bacteria and fibers such as sulfydryl cotton. After retention of the species of interest on the solid medium, they may be removed by a variety of eluents, normally an organic solvent, such as hexane, toluene or, if the species have any polarity, methanol.

Often, species of interest may be extracted from the matrix by a direct derivatization process (e.g. Grignard derivatization) that leaves the analytes in a gaseous form. If this occurs, the analytes may be swept to detection by a flow of inert gas.

### 3.3 Extraction of Species from Solid Samples

The extraction of organometallic species from solid matrices is fraught with problems. Normal wet chemical procedures for sample decomposition, e.g. fusion, acid digestion with concentrated nitric/perchloric and hydrofluoric acids and dry ashing, cannot be used as they will lead to species alteration or complete speciation breakdown. Much more gentle methods of extraction are therefore required. It is often difficult to obtain 100% extraction efficiency for all species. The analyst is then confronted with a problem. Is the portion not extracted because of incomplete extraction of one or all of the species present, or, are there one or more species present that are not extracted at all? This problem can be impossible to answer when the analyst is uncertain what species are present in the first place, which unfortunately is likely to be the case for the vast majority of samples. Spiking experiments are of limited use because in many instances standards of all the relevant species are unavailable. Examples where standards are unavailable include many of the arsensosugars (arsenoirbifuranosides) and many of the environmentally occurring species of antimony. The subject of quality control and valid analytical measurement of speciation analysis will be discussed further in section 5.

Before species extraction can be attempted, some preliminary sample preparation is normally required. For “total” metal determination, the sample is usually ground into a fine powder, but occasionally this may not be a good idea for speciation analysis as discrimination may occur against species that associate with larger particle sizes or, in the case of anoxic sediments, oxidation may occur destroying some species. This is especially a problem for samples such as soils and sediments where some species may be associated with the larger silica particles that resist grinding, whereas others may be associated with
humic substances that are more easily ground. This is not a problem for organotin speciation because it has been shown that the species are strongly bound to the fine-grained sediment fractions (<63 µm).

There are a number of extraction methods reported in the literature. New methods of extraction should first be tested on pure standards of the species of interest to ensure that no alteration to the speciation occurs. Once it has been established that the extraction protocol does not alter the speciation, further experiments to elucidate extraction efficiency from real samples may be performed. Overviews of different sample extraction methodologies have been produced, including one by Morabito\(^{(18)}\) and another by Wells\(^{(20)}\).

Extraction using an organic solvent is still proving popular. There are a number of approaches to this, depending on the analytes of interest. Arsenic species have been extracted from biological tissues using a mixture of methanol–water, with the process being accelerated by the use of an ultrasonic bath. Soxhlet extraction may also be used, but care must be taken to ensure that losses of very volatile species, e.g. organomercury compounds, do not occur. Often, a reagent such as tropolone, is used to improve extraction efficiency. This reagent also improves the extraction efficiency of many unwanted matrix constituents that may affect the chromatographic separation of the analyte species. These concomitants may have to be removed in a cleanup step prior to the analysis being performed.

Alkaline extraction using tetramethylammonium hydroxide has also been achieved. This reagent is, however, very aggressive and hence is efficient at extracting many species, but may lead to a change in speciation. Another gentle extraction method for use with biological sample preparation is that of enzymolysis. The enzymes used will depend on the sample type. For proteinaceous material, e.g. fish/shellfish or meat tissues, a protease or trypsin has been found to yield good recoveries of arsenic species. For carbohydrate-based material, e.g. plant tissue (cellulose), trypsin was found to have a poor extraction efficiency, but the enzyme cellulase has been found to have an efficiency of over 85%. A detailed protocol for an enzyme digestion is shown in Figure 1. The enzyme used here is trypsin, but the procedure is almost identical for a cellulase digestion except that an optimal pH of 5 is required. In addition to arsenic, tin species have also been determined after sample decomposition using enzymes.

Supercritical fluid extraction is a method that is growing in popularity. Specialized equipment is required, but the technique yields good recoveries. Several analytes have been extracted including organotin and organomercury compounds.

Vacuum distillation is a technique that has been used to extract organomercury species. This technique has faced some criticism by workers who claim that artificially high results are obtained because the process leads to the methylation of inorganic mercury. This underlines the problems associated with speciation analysis. Many of the materials that have been certified for methylmercury have used the vacuum distillation process for matrix removal. The validity of these materials is therefore doubtful.

Table 1 shows some of the approaches used to extract organotin compounds from mussel tissue.

![Figure 1](image-url)
eluted from the column. This step is especially necessary for analytes such as many organotin, organolead and organomercury compounds. Many of these compounds are ionic in nature and are therefore relatively refractory. They must therefore be reacted with a reagent to form volatile, completely organic molecules. For example, tetramethyl lead is nonionic and is therefore readily determined by GC. Other species such as Me₃Pb⁺, Et₃Pb⁺, Me₂EtPb⁺, Me₂Pb²⁺ and so on require derivatization.

One of the most common methods of chemical derivatization is the use of a Grignard reagent. These all have the basic structure: organic moiety—Mg—halogen, where the organic moiety may be an alkyl or aryl group. This organic moiety may be used to replace the anion (often chloride) on the analyte species, hence converting them to a volatile form. Care must be taken when selecting the Grignard reagent, to prevent confusion of the results. For example, if EtMgBr was used for derivatization, then the lead species Me₂EtPb and Me₂Pb²⁺, which are both found in environmental samples, would yield the same species once derivatized, i.e. Me₂Et₂Pb. To prevent such confusion, Grignard reagents containing propyl or butyl groups are used most often.

Many mercury compounds may also be derivatized before separation using GC. The majority of laboratories determining MeHg⁺ use an ethylation derivatization, which can be introduced via a Grignard reagent, but is more commonly based on the use of tetraethylborate. A review on the use of sodium tetraethylborate as a derivatization agent has been published. Methymercury must normally be separated from the bulk matrix before ethylation can be attempted, to prevent severe interference effects exerted by sulfur-containing compounds. Such compounds interfere with the efficiency of ethylation and may therefore cause erroneously low and imprecise data to be obtained. Extraction of the material using methanolic potassium hydroxide has been reported as being a suitable pretreatment method to achieve this.

Ionic organotin compounds must also be derivatized prior to GC separation. This may be done in two basic ways, i.e. in situ hybridization/ethylation using sodium tetrahydroborate or sodium tetraethylborate, or by an extraction followed by the use of a Grignard reagent. Assorted Grignard reagents have been used for organotin speciation. These include methyl, ethyl, propyl, pentyl and hexyl magnesium chlorides/bromides, although the ethyl and pentyl forms are most commonly used. It is reported that the alkylation is quantitative and that the derivatives are stable once formed.

The problem with some derivatization protocols is that they may not be reproducible or quantitative. This may arise because of partial destruction of the derivatizing agent or for a number of other reasons, such as impurities in the derivatization agent. If the derivatization process is not reproducible, the data obtained could be inaccurate and/or imprecise. Despite the potential problems, many laboratories experienced in speciation analysis have developed successful and reliable procedures. A brief overview of some of the applications of derivatization is given in Table 2.

Postcolumn derivatization may be necessary for some high-performance liquid chromatography (HPLC), FI or capillary electrophoresis (CE) applications. This is especially the case when either fluorescence or UV/visible absorption is used as the method of detection. Few organometallic species fluoresce or absorb UV/visible light naturally and hence after chromatographic separation they must be reacted with an agent that does. Examples of such reagents are nitrotriacetic acid (this absorbs UV/visible light) and 8-hydroxyquinoline-5-sulfonic acid (this fluoresces).

Cleanup of the sample may take several forms. Enzymolysis of solid samples does not produce a completely solid-free matrix. Instead, it leaves a suspension that has most analyte species in the liquid phase. It is common for suspensions such as these to be passed through
a 0.45-µm polypropylene filter. This method can prevent blocking of HPLC columns, but care must be taken to ensure that some species are not lost. In some cases, it may be best if filtration does not occur and that a disposable guard column be fitted prior to the analytical columns. Occasionally, after a liquid–liquid solvent extraction has been performed, a back-extraction may be necessary either to preconcentrate the analyte further, or to separate the analyte from other extracted matrix constituents. Small quantities of activated alumina or silica or silica gel have also been used to achieve this. Small columns of fluorisil have also been used to clean up extracts containing organotin compounds. As always, it is necessary to ensure that none of the species of interest are lost using the cleanup procedure.

4 SAMPLE ANALYSIS

There are a number of instrumental methods used for speciation analysis. Of these, the most common is a coupling between a separation method (chromatography) and a selective method of detection (atomic spectrometry or mass spectrometry (MS)). There are however a number of other methods in common use. The following sections will describe the methods in more detail, highlighting the relative advantages and disadvantages of each and illustrating them with selected applications.

4.1 Coupled Techniques

As described previously, this is the most common method of affecting speciation analysis. There are a number of chromatographic methods of separation of analytes and an even larger number of atomic or MS methods of detection. Methods of chromatography include HPLC, GC and CE. Occasionally ion-exchange media may be packed in microcolumns and these are then used online with a suitable detector. Such techniques are often termed FI procedures. Atomic spectrometric methods of detection include flame atomic absorption spectrometry (FAAS), electrothermal atomic absorption spectrometry (ETAAS), inductively coupled plasma atomic emission spectrometry (ICP-AES), inductively coupled plasma mass spectrometry (ICP-MS), microwave-induced plasma atomic emission spectrometry (MIP-AES) and atomic fluorescence spectrometry (AFS). The choice of which techniques to couple together will be governed by several factors including:

- the nature of the analyte
- the ease of coupling
- the sensitivity required
- the availability of the instrumentation.

In theory, most of the separation techniques can be coupled with any of the detectors, although there are practical limitations. For all of the methods, the sample is introduced as a discrete aliquot whose volume can range from 50–100 µL for HPLC down to 1 nL for CE. The individual analyte species will be detected as a transient signal. The distance between the chromatograph and the spectrometer should be kept to a minimum to avoid peak broadening as this will lead to decreased precision at lower concentrations and hence poorer limit of detection (LOD).

Harrison and Rapsomanikis have edited a book on the subject of environmental analysis using chromatography coupled with atomic spectroscopy. Although elderly, the book gives a good overview of many of the techniques available and describes numerous early applications. A paper that gives an overview of chromatography coupled with atomic spectrometry and assesses the performance of such techniques has been produced by Quevauviller. Several reviews have been made of the coupling between chromatography and atomic spectrometric detectors. These include ones by Hill et al., two by Ebdon et al. and a more recent one by Ellis and Roberts. In addition, a comprehensive review of chromatography and CE coupled with ICPMS has also been produced. The following sections will describe the coupling of each type of chromatography with atomic spectrometry in more detail.

4.1.1 Liquid Chromatography Coupled with Atomic Spectrometry

There are several types of resin used in HPLC, including anion exchange, cation exchange, reversed phase (which is often used in conjunction with an ion pairing reagent to separate the species of interest) and chelation exchange. In general, it is the ion-exchange resins that have found most use as they are less affected by matrix components in real samples. The eluent (mobile phase) used will be governed by the nature of the analyte and by the type of resin used. The eluent may be inorganic in nature, e.g. it may contain salts dissolved in water, or it may be based on an organic solvent such as methanol or acetonitrile.

HPLC may be coupled with FAAS by simply connecting the outlet of the HPLC column to the uptake tube of the nebulizer. The flow rate of HPLC is typically 1 mL min$^{-1}$, which is substantially less than the natural uptake rate of the nebulizer ($5–8$ mL min$^{-1}$) caused by the Venturi effect. If the incompatible flow rates are not compensated for, the signal will be very noisy, hence making the observation of a transient signal more difficult. The problem of incompatible flow rates may be overcome easily by placing a piece of rubber with a slit in it in the junction between the HPLC and the nebulizer uptake.
tube. The slit in the rubber tubing allows the ingress of air and this “air bleed” compensates for the differences in the flow rates. Applying this small modification to the interface leads to improved peak shapes and improved LOD because of the improved noise characteristics.

As described earlier, the eluent may be inorganic or organic in nature. There are potential problems with both types of mobile phase. Those that contain substantial amounts of dissolved solids may lead to salting up (blockage) of the nebulizer or, less likely, the slot on the burner head. If this occurs, the instrument may have to be shut down whilst the nebulizer is unblocked using a very thin piece of wire. Organic solvents often have the advantage of increasing sensitivity, because the reduced surface tension of these solvents leads to improved nebulization efficiency and hence increased sample transport to the flame. However, once in the flame the organic solvent combusts and carbon deposits may start to clog the slot on the burner head. Such deposits will cause gaps to appear in the flame, hence reducing the path length and thereby reducing sensitivity. The deposits may often be removed (often without recourse to flame extinction) by gently rubbing the slot with a noncombustible item such as a spatula.

The coupling between HPLC and FAAS is the simplest of the coupled speciation techniques because it is so straightforward and the flame is so tolerant of all the mobile phases. The largest drawback is the lack of sensitivity. For the majority of applications, the technique is incapable of detecting species at the concentrations at which they occur in the environment. Modifications to the system can be made, however, to improve the sensitivity. Optimization of the flame chemistry is the most obvious way of achieving this. For instance, when compared with an air–acetylene flame, a hydrogen flame exhibits a substantially decreased background signal in the UV region of the spectrum. This flame should therefore be the first choice for determining tin at the 224.6-nm line.

Specialized nebulizers such as the hydraulic high-pressure nebulizer increases the sample transport efficiency and hence improvements in sensitivity of ten-fold may be achieved. This nebulizer was developed especially for use with sample introduction via an HPLC pump.

Another method to increase the sensitivity is the use of a slotted tube atom trap (STAT). This is a quartz tube placed on the burner head so that the light beam from the hollow cathode lamp passes longitudinally through it. The sample is introduced via the slot in the tube and, once present, the analyte species will be atomized by the flame in the normal way. Instead of passing out of the light beam at high speed as they are in the absence of the STAT, they are contained within the tube for a longer period, hence increasing their residence time in the light beam. The analytical sensitivity is therefore improved.

Despite the overall poor sensitivity of the technique, several applications of organometallic speciation using HPLC coupled with FAAS have been published. HPLC has also been coupled with ETAAS (also known as graphite furnace atomic absorption spectrometry). In ETAAS the sample is introduced to a graphite tube which then undergoes a heating program in which it is raised to increasingly high temperatures first to dry, then ash the sample to remove as many of the matrix constituents as possible, thereby decreasing interference effects, and finally to atomize the analyte. It is a technique that yields detection limits that are typically a factor of between 10 and 100 times better than FAAS. Under normal circumstances, it is a batch technique, i.e. a discrete aliquot of sample is introduced, the temperature program is run and the result obtained and then the process is repeated for the next sample. It is this batch nature that has led to only a few applications of speciation. When HPLC is coupled with ETAAS, the eluent, which is a continuous flow of liquid, passes into the graphite tube via a transfer line. To obtain atomization of the eluting species, the normal temperature program is discarded in favor of maintaining the tube at a constantly high temperature (typically 1400–3000 °C, depending on the analyte and on the furnace design). Many HPLC separations can take in excess of 15 min to complete and running the graphite tube at such an elevated temperature for such a long time rapidly leads to tube oxidation and destruction. The high price of graphite tubes can therefore make the on-line coupling of HPLC with ETAAS prohibitive for many laboratories. Despite this, there have been several applications that have used its coupling. Some of these have been cited in the review by Ebdon et al. \(^{26}\)

Speciation analysis has also been achieved by HPLC separation of analytes followed by detection of the species off-line by ETAAS. This is achieved by collecting discrete aliquots of the eluent (perhaps 30 s worth) and then analyzing the aliquots using ETAAS in its normal mode of operation. Analysis of the eluent fractions enables an analyte concentration against elution time graph to be plotted. Although this method is very sensitive, it does suffer from some drawbacks. With so many aliquots being collected during a single chromatographic run, it is easy to mislabel an aliquot and hence confuse the issue by inadvertently “changing” the retention time of one of the species. Another problem arises when more than one species elutes close together. A continuous method of analysis may distinguish between two closely eluting species, however these may “co-elute” when aliquots covering 30 s are collected. Despite these drawbacks, the method has been used for speciation analysis by many workers.
The coupling between HPLC and inductively coupled plasma (ICP) instrumentation can be relatively straightforward. The uptake rate of an ICP nebulizer is typically 1 mL min⁻¹ which is comparable to the flow rate of most HPLC systems. The coupling is not without its problems though, and careful optimization of operating conditions and the interface is necessary to ensure optimal separation and sensitivity. Glass concentric pneumatic nebulizers, such as the Meinhard, which are frequently used for both ICPAES and ICPMS analyses, are easily blocked by dissolved or suspended solid materials. A dissolved solid content above 0.2% m/v is likely to lead to nebulizer blockage and therefore the use of these nebulizers may prove to be inappropriate for many HPLC separations (especially those that use an inorganic mobile phase containing dissolved salts). Fortunately, there are a large number of other nebulizer types that can tolerate dissolved solids more readily. Examples include the de Galan, the Ebdon and assorted other V-groove and frit nebulizers. These should be used in preference to the Meinhard when mobile phases containing dissolved solids are to be aspirated.

The next part of the sample introduction system is the spray chamber. There are a variety of different types available commercially, including the Scott double pass, miniature versions of the Scott double pass, single pass and cyclone. Each type has its associated advantages and disadvantages. The majority of spray chambers are made of glass, although inert plastic ones are also available for some designs. The Scott double pass has a large internal surface area and regions of dead volume. A large internal surface area that is made of glass will give ample opportunity for analytes such as lead (and its species) to adsorb to the walls. This may lead to some peak broadening which may affect the resolution, the precision and LOD. Similarly, regions of dead volume (i.e. regions where there is a relatively stagnant flow of transport gas and sample) also lead to memory effects. These problems are less acute in reduced-volume spray chambers, although these may be less capable of damping out noise arising from the pump and be less efficient at partitioning the droplets produced by the nebulizer according to their size. This means that larger droplets may occasionally enter the plasma, which will lead to poorer noise characteristics. Single pass and cyclone spray chambers have a smaller internal surface area when compared with the Scott double pass and also have fewer areas of dead volume.

The sensitivity, resolution and noise characteristics of the analysis depend critically on the nebulizer/spray chamber assembly. It is worth spending time in optimizing the combination as drastic improvements in performance may be obtained. A number of specialized nebulizers have been developed that operate at reduced sample flow rates (at the microliter per minute level) and therefore these may aspirate the sample directly into the plasma torch, thereby bypassing the need for a spray chamber whilst improving sample transport rate to close to 100%. Many of these specialist nebulizers therefore have improved LOD when compared with conventional pneumatic ones. Examples of some of these nebulizers include the direct injection nebulizer (DIN), the oscillating capillary nebulizer (OCN), the electrospray and the thermospray. A more detailed list of the uses of such nebulizers may be found in the annual Atomic Spectrometry Update reviews that may be found in the June edition of the *Journal of Analytical Atomic Spectrometry* (for ICPAES) or the October edition of the same journal (for ICPMS).

Other problems may be encountered during speciation analysis using HPLC coupled with ICP instrumentation. As well as possible blockage of the nebulizer, mobile phases containing dissolved solids may also block the injector tubes of some plasma torches. This again may be overcome by optimizing the injector type used. Many torches are partially demountable, i.e. the injector may be replaced by another of different internal diameter, different design or made from a different material. Dissolved solids may also block the sampling cone orifice of an ICPMS instrument. Blockage of either the injector or the sampling cone orifice will lead to excessive signal drift until, when blockage is complete, no signal is obtained. The other problem associated with coupling HPLC with plasma instrumentation is the use of organic solvents as mobile phase. These solvents tend to have a higher vapor pressure than water and hence will have higher transport efficiency to the plasma. This will often lead to plasma quenching and possibly extinction. The magnitude of the problem will depend not only on the type of solvent used, but also on the individual instrument used. Some instruments cope more readily with the introduction of organic solvents than others, because it depends on the speed and quality of the instrument’s matching network, as well as the frequency of the generator (40.68-MHz generators cope more readily than those fixed at 27.1 MHz). Another problem associated with the introduction of organic solvents when using ICPMS instrumentation is that the solvent decomposes thermally, producing large amounts of carbon deposits. These block the sampling orifice and also clog the ion lens stack. Blockage of the sampling orifice leads to signal drift and will eventually require the plasma to be turned off, so that it may be cleaned. If the lens stack becomes dirty, complete instrumental shutdown is required whilst it is cleaned. This can take several hours, which is obviously undesirable in a busy laboratory.
Because so many problems can arise through the introduction of organic solvents, in the majority of cases it is best to reduce the amount of solvent reaching the plasma. This can be achieved in a number of ways. The simplest way of doing it is to chill the spray chamber. Most spray chambers are surrounded by a jacket through which a cooling liquid is circulated. Normally this is water at a temperature of approximately 4°C, but when organic solvents are being aspirated, it is better to add antifreeze to the cooling water. In this way the temperature may be reduced to −5°C or below, depending upon the power of the chiller/circulator. The cold temperature reduces the vapor pressure of the solvent, causing less of it to be transported to the plasma whilst still allowing the analyte ions to be transported. This method is a standard procedure in many laboratories where speciation analysis is performed.

An alternative method is to use a specialized desolvation device. Some instrument manufacturers have marketed such devices, but many workers develop their own instrumentation. An example of such a device could use a mixture of IR lamps (to vaporize as much eluent as possible) followed by a selective membrane (so that vapor present preferentially passes through the membrane and is removed by a counterflow of inert gas) followed by a region chilled by Peltier coolers (which condenses out remaining organic solvent at −30°C). The condensed organic solvent could then be pumped to waste. This device can be placed between the nebulizer and the plasma torch. They are found to have a desolvation efficiency of approximately 90%, whilst not affecting the analytical sensitivity, and may be used for either ICPMS or ICPAES instrumentation.

Any solvent that does reach the plasma may be prevented from clogging the ICMS sample cone orifice or lens stack by introducing a flow of oxygen into the nebulizer gas flow. Introduction may be either via a gas blender (a device capable of introducing between 0 and 100% of a gas into the flow of another gas) and a mass flow controller, or by an alternative gas inlet that many of the more modern instruments possess. Oxygen at 4% v/v in argon is sufficient to “burn off” carbon produced by 85–100% methanol (even without a desolvation device). It should be noted that excess oxygen leads to oxidative attack of the sampling cone, which for standard nickel cones can be drastic. Excess oxygen can reduce the lifetime of a nickel cone from months to seconds. The use of platinum-tipped cones that are more resistant to oxidative attack are therefore recommended when oxygen is introduced.

Despite this list of drawbacks associated with coupling HPLC and ICP instrumentation, many workers have successfully made the coupling. This is because the problems are not insurmountable and once the instrumentation has been optimized, sensitive and reliable analyses can be performed. A comprehensive listing of the applications is inappropriate, but mention will be made of some reviews of the subject. As well as the reviews described previously that supply the reader with an indication of the range of analytes, matrices and methods used, a review that focuses on the coupling between HPLC using microbore columns and atomic spectrometry has also been published.

Liquid chromatography has also been coupled with microwave-induced plasmas (MIPs) to affect speciation analysis. MIPs can be operated economically using helium rather than the argon that is used for ICPs. Helium is a far more ionizing gas than argon (first ionization potential of 24.59 eV compared with 15.76 eV) and it can therefore be used to excite analytes such as the halogens, sulfur, nitrogen and phosphorus that are, at best, only slightly excited in an ICP. Traditionally, the problem associated with MIPs is that they are easily extinguished by liquid entering them. In early research, even a few microliters of solvent injected into a GC column had to be vented before the analyte reached the plasma. It was thought that coupling with liquid chromatography would be impossible, but by increasing the power of the plasma to several hundred watts, liquid has been introduced. This is a potential area of speciation analysis for the future, especially as many laboratories now have access to desolvation systems. In absolute terms, femtogram levels of metals and nonmetals could be determined.

Liquid chromatography has now been coupled with AFS detection, both with and without an additional MW-assisted reduction and hydride generation (HG) stage. It is worth mentioning FI techniques here, because many of the points described for HPLC are equally applicable for these methods. Many of the FI techniques used for speciation have been reviewed in a publication that contains 58 references. FI techniques use microcolumns containing ion-exchange resins or chelating resins, fibers such as sulfydryl cotton or other exchange media. Since the volume of the columns is so small, analyte separation may be achieved by using discrete volumes of eluent. With only 50–100 µL of eluent entering the plasma, the problems encountered with organic solvents are diminished. However, the use of oxygen to remove the solvent becomes complicated because of the lack of solvent entering the plasma continuously. When an inorganic eluent is used, the problem with injector and cone blockage is reduced substantially.

4.1.2 Gas Chromatography Coupled with Atomic Spectrometry

GC has been coupled less often with atomic spectrometry than HPLC. This has in part been due to the extra
sample preparation steps required for a GC analysis (i.e. derivatization reactions), but also because of the ready availability of GC/MS systems. The chief complexity of GC/atomic spectrometry is that the analytes must pass from an elevated-temperature GC column to the atom cell. For this to occur, a heated transfer line is required to prevent the analytes condensing on cool spots and hence becoming lost analytically. The transfer line should not be too hot otherwise thermal decomposition of the analyte species may occur and this may also lead to condensation of less volatile products. The construction of heated transfer lines has been discussed in the literature but the complexity depends critically on the analytes of interest. For volatile analytes, a transfer line consisting of a metal tube surrounded by a nichrome winding will suffice, but for very refractory analytes, e.g. various porphyrins which require the temperature to stay above 350–400 °C, specialist interfaces are required. Injector and column temperatures must also be optimized to prevent condensation or species breakdown.

Coupling with FAAS is one of the easier of the speciation techniques. The heated transfer line may be placed between the chromatograph and a STAT or an ordinary quartz tube with a hole in it (so that the transfer line may introduce the eluent) placed on the burner head of the FAAS instrument. The technique is relatively straightforward but suffers from a lack of sensitivity. Despite this, there have been several applications published. These include many of those cited in the review by Ebdon et al. (25) Coupling between GC and ICP instrumentation has been achieved by several workers, but at present can hardly be regarded as routine. Plasmas tend to be enclosed to prevent eye damage to operators. The transfer line must therefore often have to pass through torch box walls or doors to reach the plasma. This means that holes must occasionally be machined in the ICP instrumentation and there is a reluctance to do this.

The transfer line must usually pass as far up the injector tube of the torch as possible to prevent condensation of the analyte, without risking it picking up radiofrequency (RF) power. This is especially likely when the transfer line contains metallic components. If the line does pick up RF it may act as an aerial and transmit the power back to the gas chromatograph or possibly the operator, which could cause damage to either. Coupling of GC with ICPSMS instrumentation can lead to absolute LOD substantially below a picogram. Several workers have published reports using GC/ICPAES and GC/ICPMS.

GC has also been coupled with MIPAES. A commercial instrument has been produced, and these instruments have been used by several workers to achieve speciation analysis. An example is the determination of organotin compounds. A review of the environmental applications of GC/MIPAES has been made that focuses on sample preparation and the element-specific detection of both nonmetallic and metallic pollutants. (31)

4.1.3 Capillary Electrophoresis Coupled with Atomic Spectroscopy

Capillary zone electrophoresis (CZE) is a relatively new separation technique. It has a very low flow rate (nanoliters per minute) and at present this is not readily compatible with the uptake rate of most atomic spectrometric detectors. The extremely small sample volume used (nanoliter range) means that as much sample should reach the atom cell as possible and that the actual concentration of the analyte must be quite high (typically at the microliter per milliliter range). DINs that have a transport efficiency of close to 100% are ideal for this type of small volume sample introduction, but even these have a natural uptake rate at the microliter per minute level. Specialist interfaces must therefore be constructed to ensure that the Venturi effect exerted by the nebulizer does not draw the sample through the column at an accelerated rate, thereby ruining the separation of the species. This has been reported in a few research papers, but as yet it cannot be regarded as a routine technique. A status report detailing the requirements and potential of CE coupled with plasma spectrometry has been published. (32) Recently, there have been a number of interface designs published. (33–35)

4.1.4 Vapor Generation Coupled with Atomic Spectroscopy

4.1.4.1 Introduction

There are a number of metallic and metalloid elements that form vapors, e.g. volatile hydrides and mercury vapor, at room temperature. These vapors may then be transported in a flow of inert gas to a detector at an efficiency of close to 100%. The high sample transport rate makes the process of vapor generation very popular for these analytes because of the improved LOD. There are problems associated with the technique however, the most important of which being that not all species of an analyte form a gaseous hydride. Examples of such species include the organoarsenic compounds arsénobetaine and arsenocholine and the organoselenium compounds selenomethionine, selenocysteine and even inorganic SeIV. For species such as these to be determined, specialized sample pretreatment is necessary. This will be discussed later. Another important problem is that caused by transition metals. The presence of these elements in the sample interferes with the hydride-forming process and therefore erroneously low hydride formation yields may result, causing an underestimation of the true concentration.
of the analytes. This problem can be alleviated by the addition of masking agents such as L-cystine or L-cysteine.

Several different methods of detection are available for HG techniques. These include atomic absorption spectrometry (AAS), atomic emission spectrometry (AES), ICPAES, ICPMS and AFS. The technique of AFS has the advantages of being very sensitive and having a linear range that covers several orders of magnitude. Commercial instruments have been marketed that have a vapor generation unit coupled with an element-selective AFS detector. Although relatively cheap, they are often the first choice of instrumentation for analytes such as mercury, that can be troublesome by other methods. The coupling between the vapor generation system and the detector is relatively straightforward, because the sample is transported as a gas. It should be noted however that some plasma-based instruments may be disturbed by excessive amounts of hydrogen that may be a product of the hydride-forming reaction. Similarly, the presence of large volumes of hydrogen going into the flame of an AFS instrument may also lead to flame perturbation, dilution and decreased sensitivity. The chemistry of the hydride-forming process will therefore have to be optimized to prevent flame or plasma perturbation and decreased sensitivity. It is therefore essential to consider the system as a whole rather than optimizing the hydride-forming process and the detection process independently.

For normal HG analysis the sample is mixed with a reductant in an acidic medium and the analytes form gaseous hydrides that may be swept from a gas–liquid separator by an inert gas. Several reductants may be used, but sodium tetrahydroborate is the most common for many analytes although tin(II) chloride is often used to reduce mercury ions to elemental mercury vapor. A good overview of the use of sodium tetrahydroborate (also known as sodium borohydride) for elemental speciation has been produced by Howard.

4.1.4.2 Cryogenic Trapping Methods Some simple organometallic forms can be separated from others by cryogenic trapping. In this process, the hydride of the analytes should be formed in the normal way, but instead of transportation directly to the atom cell they may be trapped in a U tube packed with a silanized chromatographic support or glass beads. The U tube should be immersed in liquid nitrogen, hence freezing the gaseous hydrides. The U tube may then be removed from the liquid nitrogen and allowed to rise to room temperature (or possibly above room temperature if a heating device is used). If this is performed whilst flushing an inert gas through the system, the individual hydrides revert to gaseous form at their own respective boiling points and are transported to the detector. In this way a pseudochromatographic separation may be achieved. Detection may be by atomic emission, atomic absorption or ICPMS. Often the atom cell is a quartz T-piece placed on the burner head of an atomic absorption instrument and heated either by the flame or electrothermally. The T-piece operates in a similar manner to the STAT, i.e. it enhances sensitivity by increasing the residence time of the analyte in the light beam. A masking agent (L-cysteine) and a cryogenic trap have been used to determine inorganic arsenic, monomethylarsonate and dimethylarsinate. The cysteine has the added bonus of giving uniform sensitivity for all the species determined. A schematic diagram of the overall apparatus for HG used in conjunction with cryogenic trapping is shown in Figure 2.

4.1.4.3 Chromatography Coupled with Hydride Generation Techniques Cryogenic trapping experiments have been used in association with chromatographic separation of the species prior to the HG step. Both GC and, more commonly, HPLC have been coupled with HG. A chromatographic separation is of more use than simple cryogenic trapping because it allows the determination of more analyte species, but cryogenic trapping can allow concentration of the analyte.

For compounds such as those described earlier that do not form a hydride, several on-line techniques have
been developed that transform the species in a known and reproducible way. If these methods are used, then all the species present in a sample may be separated chromatographically and then transformed, perhaps to a single species that forms a hydride. The components are then detected as a series of transients in a time-resolved way. Several on-line methodologies are available. The use of a strong oxidizing agent such as potassium persulfate is known to decompose compounds such as arsenobetaine. Other methods include photooxidation and the use of heating. Many reported methods have used one or more of these techniques to transform the species into a reducible form. The use of MW ovens on-line has therefore found use in this area as the MWs heat the eluent very rapidly thereby assisting in both the thermal and chemical decomposition of the species. Numerous examples exist in the literature. Some of these on-line methodologies are presented in Table 3. A thermal bath may also be used, but this acts far slower than an MW oven and is therefore less efficient for on-line techniques. In general the efficiency with which sample decomposition occurs decreases in the order MW digestion > UV photolysis > thermal bath. Addition of a reagent such as persulfate will accelerate the decomposition processes further.

The majority of applications involving speciation via chromatography coupled with HG and atomic spectroscopic detection have probably involved the determination of As, although other analytes such as Sn and Se have also been determined effectively.

The use of such techniques with detection by AAS yields LODs of approximately 0.5–10 µg L\(^{-1}\) (which for an injection volume of 0.1 mL leads to an absolute LOD of 0.05–1 ng), depending on the species of interest. For some analytes, the use of AFS or ICPMS detectors will lead to improvements in the LOD. Some research papers have now been published linking HPLC/UV/ICP-AES. This application may be used to photolyze arsenobetaine and arsencolcholine prior to arsine generation and detection. The coupling between chromatography, HG and assorted detectors is likely to be exploited more often in the future for speciation analysis in an ongoing attempt to improve versatility and sensitivity. A schematic diagram of the instrumentation used is shown in Figure 3.

4.2 Other Methods of Speciation

The coupling of a separation technique (chromatography) with an element-selective (or specific) detector (such as atomic spectroscopy) is a common method of speciation analysis. There are however several other techniques

![Figure 3](image-url) Schematic diagram of the instrumentation required for the determination of organometallic compounds by HPLC/HG/AAS.
that have been used, although some of them suffer from poor sensitivity or interferences. Many still use chromatography to separate the species but then use conventional detectors. Examples include GC separation followed by MS (GC/MS). This mature technique has been used, for example, for the speciation of mercury in fish and water samples, trimethyllead in rainwater, arsenic speciation in an aqueous environment and the determination of an assortment of analytes (tin, antimony and bismuth compounds) in landfill and fermentation gases. Other detectors that have been used in conjunction with GC for speciation analysis include the flame photometric detector (FPD), which has found special use for tin speciation, the FID that has been used for several analytes, including arsenic compounds, and the electron capture detector (ECD). Each has its own specific advantages and problems. The FID is quite sensitive, but will give a response to any compound that contains carbon. Therefore, for many sample types, the chromatograms may have a plethora of peaks, only a few of which relate to the species of interest. Other detectors such as the FPD, which is also very sensitive, may suffer from interference effects. Only a single wavelength isolation device is used, which allows a broad band of radiation to be detected. Therefore any components in the sample that emit light at a wavelength similar to the analyte will also be detected. There is often a need for matrix elimination when this technology is being used. This is normally possible with the aid of derivatization reactions, but some sample types may still be problematic. One such type occurs when organotin compounds are to be determined in a sample that contains numerous volatile sulfur compounds. The sulfur will interfere strongly with the detection of the tin. When used for tin speciation, the FPD can yield a LOD of 0.02 ng mL\(^{-1}\). The technique can therefore be regarded as being extremely sensitive (more so than coupled HPLC/ICPMS). The latter technique however would not suffer the interference from sulfur. The ECD is very sensitive for certain elements, e.g. the halogens, but not for most metals, and therefore its application to environmental analysis is limited.

Similarly, with HPLC separations, the traditional methods of detection, i.e. UV/visible absorption and fluorescence, may be used. The UV/visible method has poor sensitivity. Fluorimetric detection has also been reported. This method yields high sensitivity, but often requires postcolumn derivatization. The method has been used to speciate aluminum complexes and organotins in waters. As with all fluorescence-based detection techniques, the method is very sensitive and has a long linear range.

CE has also been used in conjunction with an array of different detectors. These include UV detection for assorted arsenic compounds and for the determination of methylmercury in fish and crab. Amperometric detection has also been used for mercury species. This latter application enabled a LOD of 0.2 ng mL\(^{-1}\) for Hg\(^{2+}\) and 3 ng mL\(^{-1}\) for methylmercury, which for a 40-nL injection volume relates to an absolute LOD of 8 fg and 120 fg, respectively. The LOD by this technique is therefore extremely impressive, but it does suffer from the drawback of only being able to detect cationic mercury species that are electrochemically active. It was reported that in the analysis of a sediment at least one mercury species was unsuitable for detection. Another novel coupling has been CE with particle-induced X-ray emission (PIXE). An overview of speciation studies using CE has also been published.\(^{(37)}\) Many applications require postchromatographic derivatization to transform the species into a state where they may be detected more easily. The current trend for speciation analyses is to couple several different techniques together in an attempt to improve applicability and sensitivity. CE has been coupled with HG prior to detection of the analytes (arsenic species) by ICPAES.

Assorted mass spectrometric methods other than GC/MS have also been used for speciation analysis. These include several versions of liquid chromatography/MS, such as liquid chromatography/electrospray/MS/MS (tandem mass spectrometry) and ionspray-MS. As the instrumentation required becomes more readily available and reliable, these approaches can be expected to grow in popularity.

Electrochemical techniques have also been used for speciation analysis. These methods are inexpensive and are also relatively portable. They are therefore commonly found aboard ships and hence are popular with oceanographers and marine chemists. Often these techniques are used to differentiate between oxidation states, but may occasionally be used to analyze for organometallic compounds or compounds that are associated with an organic moiety, e.g. ligands. An overview comparing electroanalytical techniques with atomic spectrometric techniques has been made by Bersier et al.\(^{(38)}\) Several other papers of interest in this area may be found in the literature. Examples include the dissolved phase speciation of zinc in the Humber Estuary,\(^{(39)}\) cadmium speciation and complexation by natural organic ligands in fresh water\(^{(40)}\) and the soil solution speciation of lead.\(^{(41)}\) In this latter paper, “total” lead was determined by ETAAS, and the labile lead determined by differential pulse anodic stripping voltammetry (DPASV). The labile Pb values were used to calculate the free Pb\(^{2+}\) activity based on the assumption that organolead complexes are not DPASV labile. The techniques may be problematic. For instance, the determination of organolead compounds may be interfered with by the presence of inorganic lead. This must be removed prior to analysis by the use of a resin such as chelex, by ethylenediamine tetraacetic acid or by coprecipitation.
with barium sulfate. The sample preparation for these techniques therefore tends to be complex. Differential pulse polarography and differential pulse cathodic stripping voltammetry have been used to determine selenium species. It has been found that the presence of some transition metals (e.g. Cr\textsuperscript{VI}, Cu\textsuperscript{II}, Mo\textsuperscript{VI}, Ni\textsuperscript{II}, Zn\textsuperscript{II} and V\textsuperscript{V}) caused interferences and that these too had to be removed by the use of chelex prior to analysis.

The other drawback with electrochemical techniques such as anodic stripping voltammetry is that they are limited to only certain elements, i.e. only certain elements are electroactive. These metals include copper, lead, cadmium, zinc thallium, antimony, tin, bismuth, chromium cobalt, manganese, nickel and mercury. Fortunately, these are the elements of most environmental interest, but these limitations could be prohibitive for other sample types.

Neutron activation analysis has also been used as an offline detector for HPLC separations of different species. This technique can hardly be described as routine though.

NMR has been used to elucidate the structure of many arsenosugars found naturally in seaweed and algae. The poor sensitivity of NMR (even Fourier transform instruments) means that the analytes of interest have to be present at an appreciable concentration. In one paper, the authors started with several kilograms of material so that they could extract sufficient analyte to be determined.\(^{42}\) To make the spectra more simple to interpret, purifications and separations of the species were performed using gel permeation chromatography or ion-exchange chromatography prior to the \(^1\text{H}-\text{and}^{13}\text{C-NMR analysis}.\) The determination of arsenolipids in seaweed has also been performed in a similar manner.\(^{43}\) Other analytes have also had their structure elucidated using NMR spectroscopy. Examples include the speciation of copper in the bovine rumen environment\(^{44}\) and the reaction of aquatic humic substances with aluminum.\(^{45}\)

The latter paper is typical of an NMR-based speciation analysis, because aluminum is the most commonly determined analyte by the technique.

A multimethod approach to studying humic compounds and metal speciation has been described by Petronio et al.\(^{46}\) These workers used both NMR and IR spectroscopy as well as elemental analysis and thermogravimetry to study metal–ligand structures. In another paper,\(^{47}\) the Cr\textsuperscript{III} binding abilities of humic acids were determined using NMR and IR spectroscopy. It was found that the bonding was between the Cr and a carboxylate group.

### 5 METHOD VALIDATION

As with all types of analytical chemistry, methods should be validated to ensure that the data being produced are both accurate and reproducible. Ideally, all species should be isolated from the matrix with 100% efficiency and with no change to the speciation. This is rarely the case. Often extraction efficiency is less than 100% and the analyst must decide what course of action to take. Many species are lipophilic (i.e. they dissolve in the fat layer of biological materials such as fish). These species will be extracted very poorly by a polar solvent system such as methanol–water which has been used by several workers to extract arsenic species. On such occasions, the analyst must try to determine whether the species that have been extracted are the only ones present in the sample and that there was a small amount of them dissolved in the fat; or whether there may be one or more species present only in the fat that were not extracted. Several other problems exist for speciation analysis. Often, standards of all the relevant species are unavailable commercially. This can therefore cause problems with the identification of some species and will definitely cause problems when quantification is attempted. The absence of standards will also make spiking/recovery experiments more difficult. Examples of species that do not have commercially available standards include many of the arsenosugars and many antimony species. Ideally, CRMs that contain all the relevant species in the matrix of interest would be available. Unfortunately this is rarely the case. Despite these problems, method validation can be achieved under certain circumstances. Several papers have been produced that describe quality control techniques for speciation analysis. These include one that concentrated on hyphenated techniques.\(^{48}\)

#### 5.1 Mass Balance Data and Spiking/Recovery Experiments

Mass balance data can be obtained if the sum of the analytes extracted are compared with the “total” amount of analyte. Therefore, if a water sample is to be analyzed for tin species, the water could be aspirated into a spectrometer (e.g. ICPMS) directly and the “total” concentration of tin determined. If a separate subsample then undergoes speciation analysis using perhaps HPLC/ICPMS, then the sum of the species should be the same as the “total” concentration. Similarly, if the material of interest is a solid, “total” concentrations of analyte may be determined by a strong acid digestion, and the speciation data may be obtained after an extraction technique is performed on a separate subsample. If the sum of the species equals the “total” concentration, then it is usually assumed that extraction is 100% efficient. This method does not account for any speciation changes during the extraction process. A summary of how mass balance data is obtained is shown in Figure 4. An example could be arsenic speciation in fish.
tissue using an extraction method with methanol–water and a “total” digest using nitric acid and hydrogen peroxide. If the “total” concentration was found to be 20 µg g\(^{-1}\) and the sum of the species was found to be 17.5 µg g\(^{-1}\) (as arsenic, not the species), then the overall extraction efficiency is given by Equation (1):

\[
\frac{17.5}{20} \times 100 = 87.5\%
\]  

(1)

The recovery of the arsenic species may then be corrected for the losses observed during extraction (i.e. the concentrations of all observed species multiplied by the recovery factor, in this case 100/87.5). As described previously, this method is not infallible because there may be one or more species present that have 0% extraction efficiency whilst the others have 100% efficiency. By multiplying the results by the overall extraction efficiency, incorrect answers may be obtained.

Spiking/recovery experiments are another common way of method validation. It should be noted that the method of spiking is similar to that used during normal analysis, i.e. a small volume of a concentrated standard is spiked into a subsample and allowed to equilibrate (“soak in”) for at least 24 h. The now dry sample can then be extracted in the normal way. Unspiked subsamples should also be extracted in the same manner. It is also worth noting that the spike should be approximately the same concentration as that already present in the sample (or at least within a factor of 2–5). If the spike concentration is far in excess of this, unreliable data will be obtained. Similarly, the spike should be allowed to equilibrate for at least 24 h to ensure that it behaves at least partially like the analyte species already present in the sample (i.e. it has time to become adsorbed or chemisorbed to the matrix). Although this situation is not ideal, because it can take weeks or months for the same process to occur naturally in the environment, it is the only practical way of doing it. The problem does not arise with water samples because simple mixing is sufficient to ensure equilibration.

This method of validation is useful when standards of the species to be determined are available. It allows the recovery of individual species to be determined, so the recovery factor of each can be used to estimate the true concentration of that species in the sample.

If spiking/recovery experiments are used in conjunction with mass balance data, then reasonable estimates of the speciation can be obtained.

5.2 Certified Reference Materials

Speciation analysis is a subject that has only relatively recently become hugely popular. It is for this reason that the number of CRMs available with any speciation data are limited. There are an infinite number of environmental samples occurring naturally and several elements that form organometallic species. It is an impossible task to speciate all relevant analytes in all possible sample matrices and therefore manufacturers of CRMs have concentrated on only a few of most interest. A list of some of the CRMs available from different manufacturers is given in Table 4. In addition to these, there are also materials that, although not certified, do have consensus values agreed by several laboratories. The dogfish reference muscle DORM-1 available from the National Research Council Canada is one such material. Its total arsenic value is 17.7 µg g\(^{-1}\) and its arsenobetaine concentration (as arsenic) is generally regarded to be in the range 15.5–16.5 µg g\(^{-1}\).

As described previously, ideally a certified material with speciation data of every matrix would be available. This however is not the case. Even those samples that are ostensibly the same type may have only limited use. Several certified sediments are available with data for organotin compounds, but the actual matrix of the

</table>
sediments may differ widely. Some have a sandy matrix, whereas others may be very rich in humic acids and other organic materials. A given extraction method may have a higher efficiency for some matrices than others. Therefore, if sediments are to be analyzed, it may not be sufficient to analyze any certified sediment, as misleading data may result. Instead, it is necessary to pick a certified sediment that resembles the matrix of the sample sediments as closely as possible.

The difficulty in certifying samples for speciation data has been highlighted by unsuccessful certification campaigns. For example, The European Community attempted to produce a simulated rainwater sample containing organolead species. It was found that the lead species were unstable and that losses occurred. Another example was for the organotin speciation of a highly polluted sediment. It was found that data were obtained with an unacceptably high uncertainty and that the laboratories that relied on a derivatization step produced the least reliable results. Despite these setbacks, the production of certified materials for speciation analysis continues to grow. Quality procedures necessary to produce CRMs for speciation analysis have recently been reviewed in an excellent book by Quevauviller.

5.3 Other Methods of Validation

The analysis of an appropriate CRM is the best procedure for method validation. Unfortunately these are not universally available for every speciation problem. The use of two completely different analytical methods is the next best approach but again often only one analytical method, or extraction procedure, is possible practically. Alternatives such as standard additions or spiking, as discussed above, have to be used.

The use of isotope dilution analysis (IDA) can also assist in obtaining accurate results. Although a full description of isotope dilution is beyond the scope of this text it may readily be found elsewhere. Basically, the added isotope acts as an intrinsic internal standard that can overcome problems associated with incomplete extraction, but cannot correct for changes in speciation. It can however be a useful method of determining when changes to speciation occur. Several papers have been published that have used IDA for speciation purposes. In addition, two book chapters have also been published. Where the isotopically enriched spike is added in the form of the species to be determined, additional value is obtained.

Although not strictly a method validation technique, it is worth mentioning the reporting of the data. For normal analysis, it is sufficient to give a “total” concentration of an analyte. For speciation analysis though, it is necessary to describe what actually has been measured, i.e. the species or the element. For instance, if the total arsenic concentration is 20 mg kg\(^{-1}\), it is necessary to describe the concentration of the species in terms of arsenic rather than arsenobetaine and so on. This will prevent confusion. If the analyte species’ concentration is reported, it is necessary to say so in the report.

6 CONCLUSIONS

Speciation analysis is a still relatively young area of analytical chemistry, even though it gives far more information on the overall toxicity of a sample and may be used to elucidate the reactions performed by naturally occurring phenomena. A list of the elements that have been speciated in environmental samples is shown in Table 5. A diagram of the LOD achievable using different techniques is indicated in Figure 5. The LODs have been quoted as absolute amounts for chromatographic based techniques, but it is worth remembering that the absolute LOD is dependent on the discrete volume introduced. Techniques such as CZE, which have a very impressive absolute LOD but only require nanoliter injection volumes, therefore require the analyte species to be relatively concentrated (e.g. at the microgram per milliliter level). There are several problems associated with the procedures, with methods that work for one sample not necessarily working for another. The development of robust and universal methods is therefore still a great challenge. Method validation is still an area under expansion as

the requirement for certified materials far outstrips their supply. As yet, the number of CRMs available is very limited, with some analytes, e.g. antimony compounds, not being certified in any matrix.

It is envisaged that as analysts adapt their methodologies to other sample types, whilst looking for more analytes at a lower concentration, the use of hyphenated techniques will continue to grow. The use of multiply hyphenated techniques is already appearing and this is likely to increase further to improve the LOD and enable more analytes to be determined. Similarly, more efficient methods of sample extraction and preconcentration will also be developed.

REFERENCES

The use of pervaporation in analytical chemistry is a relatively new development. Pervaporation is a separation technique for the removal of volatile analytes or their volatile derivatives from the sample matrix. It can be defined as the integration of evaporation and gas diffusion in a single module. The volatile substances present in a heated donor phase evaporate through a porous membrane and the vapor condenses on the surface of a cool acceptor stream on the other side of the membrane. The temperature difference across the membrane is the driving force for the separation. An important characteristic of analytical pervaporation is the presence of a constant-volume air gap between the sample in the donor chamber and the membrane, which hinders any contact between them, thus avoiding clogging and/or deterioration of the membrane.

Pervaporation can also be used for sample pretreatment, e.g. for solid samples where leaching and derivatization of the analytes are done simultaneously. In this article, the applications of analytical pervaporation that have been developed so far are discussed. Special attention is paid to its use as an alternative to gas diffusion, to liquid samples containing solids in suspension and/or corrosive, to solid samples in which a single analyte must be determined, to multideterminations, and to speciation studies. The integration of this separation technique with detection and the coupling of a pervaporator to a gas chromatograph (GC), which constitutes a valid alternative to headspace sampling, is also commented upon.

1 INTRODUCTION

Recent developments in automatic continuous analyzers have led to the use of nonchromatographic continuous separation techniques for the determination of one or more analytes, the separation of components into groups, and interference removal. The different principles on which current nonchromatographic continuous separation techniques rely overcome a variety of analytical problems associated with preliminary operations, which are normally complicated, slow, variable, difficult to control, labor-intensive, occasionally hazardous to both laboratory personnel and the environment, and the sources of major errors. These techniques (which can be applied in various areas, including environmental pollution, clinical and pharmaceutical chemistry, and food and industrial analysis), have emerged as very promising alternatives to chromatographic techniques on account of such assets as reduced human participation, easy on-line coupling with many instruments, diminished errors and hazards, increased sample throughputs, and sparse sample and reagent consumption. Nonchromatographic continuous separation techniques can improve the sensitivity of a method via preconcentration, and its selectivity through avoidance of matrix effects or particular interferents. Coupling two equal or different continuous separation techniques can be a useful way of dealing with complex samples by exploiting a synergistic effect.\(^{(1)}\)

Membrane-based nonchromatographic continuous-separation techniques are especially useful for increasing
In some cases, they also permit analyte preconcentration, thereby resulting in improved sensitivity. Continuous gas diffusion, whether in isolation or coupled (in series or parallel) with other separation techniques such as dialysis and ion exchange, makes an excellent choice for achieving high selectivity and sensitivity. However, these techniques suffer from two serious drawbacks, namely potential clogging of membrane pores by suspended particles or components of a high molecular weight occasionally present in the sample plug, and deterioration of the membrane through contact with the sample. Both shortcomings can be overcome by using pervaporation (so-called in order to emphasize that the analyte or its reaction product, known as the “permeate”, undergoes a phase change from liquid to vapor before reaching the membrane). Pervaporation has long been employed in industry, in competition with other traditional separation processes (e.g. distillation, extraction, adsorption); by contrast, it has scarcely been used for analytical purposes. On the laboratory scale, analytical pervaporation can be defined as the integration of two different analytical separation principles (evaporation and gas diffusion) in a single micromodule. Major simplification and miniaturization of the experimental set-up are thus obtained, and human participation is also reduced so as to increase analytical quality and productivity. Pervaporation is in principle a separation technique for the removal of volatile analytes or their volatile derivatives from the sample matrix but can also be used for sample pretreatment, e.g. for solid samples where leaching and derivatization of the analytes are done simultaneously.

2 PRINCIPLES OF PERVAPORATION

Industrial pervaporation \(^{(2-4)}\) selectively separates a liquid feed mixture by partial vaporization through a nonporous polymeric membrane. The separation is not based on relative volatilities, as in the case of distillation or evaporation, but rather on the relative rates of permeation through the membrane. The mixture is circulated in contact with the membrane and the permeating component diffuses through it. A vacuum (vacuum pervaporation) or sweeping gas (sweeping-gas pervaporation) is applied to the membrane on the permeate side and the permeating component desorbs from the membrane as a vapor, which can be collected or released, as required. The driving force for separation is the chemical potential on both sides of the membrane. The permeating component is transported through the membrane because its partial pressure on the permeate side is lower than that in the saturated vapor. \(^{(5)}\)

Separation from mixtures is obtained because the membrane transports one component more readily than the other, even if the driving forces are equal. The effectiveness of pervaporation is measured by two parameters, namely flux, which determines the rate of permeation, and selectivity, which measures the membrane’s separation efficiency (controlled by the intrinsic properties of the polymers used for the membrane). The coupling of fluxes affecting the permeability of a component present in a mixture can be divided into two parts, namely a thermodynamic part, expressed as solubility, and a kinetic part, expressed as diffusivity. In the thermodynamic part, the concentration change of one component in the membrane due to the presence of another is caused by mutual interactions between the permeates in the membrane, in addition to interactions between the individual components and the membrane material. On the other hand, kinetic coupling is due to the dependence of the concentration on the diffusion coefficients of the permeates in polymers. \(^{(3)}\)

For a binary mixture of components A and B, the flux can be expressed for the entire permeate \((J_T = \text{total flux})\) or for each component \((J_A, J_B = \text{flux of components A and B, respectively})\), having dimensions of mass/(area \(\times\) time). The flux can be calculated provided that the mass of the permeating component, the membrane area, and the time of measurement are known. Also it can be defined according to Equation (1):

\[
J_i = \frac{-L_i \Delta \mu_i}{l}
\]

where \(L_i\) is the phenomenological diffusion coefficient, \(\Delta \mu_i\) the chemical potential driving force across the membrane, and \(l\) the membrane thickness.

The selectivity is given by the ratio of the mass fractions of components A and B for the permeate and feed. In the case of selective permeation of the component A, Equation (2) applies:

\[
\alpha^A_B = \frac{y_A / y_B}{x_A / x_B}
\]

where \(x_A\) and \(x_B\) are the mass fraction of components A and B, respectively, in the feed, and \(y_A\) and \(y_B\) those in the permeate. A value greater than unity indicates selective permeation of A over B, whereas a value lower than unity indicates selective permeation of B over A. The selectivity is dimensionless and occasionally described as an enrichment factor \(\beta\), which is the ratio of a component concentration in the permeate to its concentration in the feed. \(^{(3)}\)

The process is favored by increased temperatures, which result in a vapor pressure difference that increases the permeability of the substances through the membrane by allowing the diffusion of permeated molecules and decreasing interactions between permeates. The membrane morphology (rubbery/glasy polymers) also influences the efficiency of the separation technique.
Even though pervaporation appeared at the beginning of the 20th century, research activity in this field for industrial applications increased in the 1970s owing to the energy crisis and has been focused on three types of separation: the dehydration of an aqueous–organic binary mixture by using water-selective hydrophilic membranes (e.g., dehydration of ethanol produced by fermentation in the sugar refinery of Bethénilville in France), the permeation of organic(s) from an aqueous–organic mixture using hydrophobic membranes (concerning solvent recovery, hazardous waste treatment, water purification, and beverage processing) and the permeation of a particular organic from an anhydrous mixture (e.g., aromatics–paraffin, branched hydrocarbons–paraffin, olefins–paraffin, and isomeric mixtures), which is not yet viable with currently available membranes. The advantages of pervaporation over conventional industrial separation processing can be summarized as follows: energy savings, easy separation of azeotropic mixtures, easy dehydration of multicomponent mixtures, no contamination of the product with entrained compounds, no environmental pollution caused by treatment of entrained compounds, easy operation, space savings, and easy installation on-site as the pervaporator is skid-mounted.

Analytical pervaporation is a process in which volatile substances in a heated donor liquid phase evaporate through a porous hydrophobic membrane. The vapor condenses on the surface of a cool acceptor stream on the other side of the membrane. Surface-tension forces withhold the liquids from the pores and prevent direct contact between them. A temperature difference, which results in a vapor pressure difference across the membrane, provides a strong driving force for the separation, which also occurs in the absence of temperature gradient. Evaporation will occur at the solution surface if the vapor pressure is greater than that at the condensate surface. One important feature of the pervaporation module used for analytical purposes is the air gap between the donor stream and the hydrophobic membrane, which avoids any contact between them and diminishes the problems associated with fouling of the membrane.

The mechanism of transport by pervaporation can be described by the solution-diffusion model, which comprises the following steps:

- evaporation of the analyte into the air gap;
- sorption into the membrane on the downstream side;
- diffusion of the sorbed component through the polymer matrix;
- desorption into a liquid or gas phase on the upstream side.

The last three steps are also included in industrial pervaporation.

Several applications of laboratory pervaporation have been developed for the determination of analytes or their reaction products in both liquid and solid samples, integrated or not with detection. Since pervaporation is a very mild process that can be operated at the required temperature and needs no high pressure, cross-flow velocity, or additional chemical, it is particularly well adapted for integration with fermentation processes.

### 3 THE ANALYTICAL PERVERSORATOR

A laboratory-scale pervaporator is a very simple unit that can be designed and built in the laboratory according to requirements. Two different parts must be considered in it: the body of the separation module and the membrane.

#### 3.1 Body of the Analytical Pervaporator

The body of the pervaporation module consists of the following parts (Figure 1): a lower, donor chamber through which the feed stream, containing the analyte or its volatile product, is circulated (a); spacers of varying thickness, from 2 to 10 mm, which can be placed below and/or above the membrane support in order to increase the volumes of the corresponding chambers (b); a thin membrane support (ca. 1 mm thickness) (c); an upper, acceptor chamber with inlet and outlet orifices through which the acceptor stream is circulated and in which the gaseous analyte is collected (d); and fluid-circulating thermostats (e) which increase the difference

![Figure 1 Parts of a conventional pervaporation module. (a) Donor/sample chamber; (b) spacer; (c) membrane support; (d) acceptor chamber; (e) fluid-circulating thermostats; (f) connectors.](image)
in temperature between the two chambers, so improving the pervaporation process. The whole module can be made of methacrylate, which permits continuous checking during experiments, although a Perspex pervaporation unit has also been proposed recently. The membrane support is made of polytetrafluoroethylene (PTFE). The upper and lower chambers (and the membrane support) are kept together by screwing them. The temperature is adjusted by circulating a fluid with the appropriate temperature, by inserting the module in a thermostated waterbath, by immersing the module in a thermostated waterbath, by inserting an electronic temperature controller, or by focused microwaves.

This kind of unit has been used in combination with a flow-injection (FI) manifold for the determination of various analytes in liquid samples; the separation is followed by detection and the donor chamber is usually heated by a conventional water bath. Alterations of either the auxiliary dynamic manifold or the pervaporator itself are required when (i) the pervaporation process is assisted by focused microwaves, (ii) the separation step assists in the continuous monitoring of an evolving system, (iii) solid samples are used with no pretreatment, and (iv) pervaporation is integrated with detection.

(i) The module used for microwave-assisted pervaporation is similar to that shown in Figure 1, but with smaller dimensions (external diameter less than 35 mm) so that it can be accommodated inside the microwave vessel. Since no metal parts are admitted in the microwave chamber, the cell (screws included) is constructed entirely in PTFE/methacrylate.

(ii) When the pervaporation unit is used for the continuous monitoring of a fermentation process or the determination of analytes in samples containing suspended particles, the module in Figure 1 must be altered by increasing the diameter of both channels (inlet and outlet) of the donor chamber, which could otherwise be clogged.

(iii) For solid samples, a septum is placed at the inlet of the lower chamber through which the reagents are injected with a syringe. The outlet of the same chamber is shut with a screw so as to avoid leakage and the consequent analyte losses.

(iv) When separation and detection of the volatile species occur simultaneously, a hole is drilled at the center of the upper chamber top of the pervaporation cell in order to accommodate the sensor by means of suitable adapters. This module can be used for liquid and solid samples; the flow of the acceptor stream is stopped during measurement in order to permit the accumulation of the analyte released from the matrix during the process and hence increase the sensitivity of the method.

3.2 Membranes

In general, permeability in glassy polymers (e.g. cellulose) is lower than in rubbery polymers (e.g. poly(dimethylsiloxane) PDMS) and selectivity is primarily determined by the molecular dimensions of the permeating species. It has also been demonstrated that both the pore size of the membrane and its thickness strongly affect the pervaporation process and its selectivity. The polymers used as membranes for the pervaporation process are similar to those employed for gas separation and have a “dense” nonporous macroscopic structure; the difference between the two techniques lies in the transport mechanism and arises mainly from a large difference in affinity between the permeating molecules and the polymeric membrane.

The membranes used for analytical pervaporation are hydrophobic membranes of the types usually employed in ultrafiltration and gas-diffusion processes. In practice, PTFE is the most frequently used membrane material, followed by hydrophobic poly(vinylidene fluoride) (PVDF). Ultrafiltration membranes are very thin, which, in combination with the large surface area of both the donor and acceptor chambers, leads to their easy bending. This results in a change in the flux of the permeating component through an altered membrane area, and hence in a change in the efficiency of the process; as a consequence, the membranes must be changed fairly often. Gas-diffusion membranes are not so easily bent because of their thickness, so the same membrane can be used over longer periods. The pore size of the membrane (or its directly proportional thickness) influences the efficiency of the process and hence the sensitivity of the method; as a result, it affords application to samples with variable analyte concentrations.

4 THE AUXILIARY MANIFOLD

A typical flow injection/pervaporation configuration is shown in Figure 2(a). The sample is either injected into the carrier stream or directly aspirated and mixed (or not) with the reagent (R1), in passing through the mixing coil, RC1. The resulting stream reaches the lower part of the pervaporation cell, which is thermostated at the required temperature. The volatile compound evaporates, diffuses through the hydrophobic membrane, and is collected in an appropriate solution with which it may or not react.
The outlet of the acceptor chamber can be either led to the detector or merged with another reagent stream to give the finally detected product.

5 TYPES OF ANALYTICAL PERVAPORATION

The qualifiers “continuous” and “discontinuous” for pervaporation are used to refer to different aspects of the process. In fact, analytical pervaporation is a continuous technique because, while the sample is in the separation module, mass transfer between the phases is continuous until equilibrium is reached. “Continuous” also refers to the way the sample is introduced into the dynamic manifold for transfer to the pervaporator. When the samples to be treated are liquid, the overall manifold to be used is one such as that shown in Figure 2(a). The sample can be continuously aspirated and mixed with reagent(s) if required (continuous sample introduction). The “discontinuous” mode of sample introduction is performed by injection of a liquid sample, either with an injection valve of the manifold, followed by sample transport to the pervaporator, or by means of a syringe furnished with a hypodermic needle, directly into the lower/donor chamber of the separation module when no dynamic manifold is used. In any case, the sample reaches the lower chamber of the separation module and the volatile analyte (or its reaction product) evaporates, diffuses across the membrane, and is accepted in the upper chamber by a stream or static solution that drives it continuously or intermittently, respectively, to the detector (except in the cases where separation and detection are integrated). The pervaporation unit can also be used with solid samples in a discontinuous way. In this case, the sample is weighed in the donor chamber; then, the module is tightly closed and the reagents, if required, are injected through septa. The manifold used in this case is shown in Figure 2(b). A heating source at the appropriate temperature, acting on the donor chamber, starts the process. In this case, the separation module is employed as a leaching and reaction vessel with or without integrating the detection step. Sample manipulation and losses of analyte are hence limited.

The flow of donor (sample) and acceptor solutions (lower and upper chamber, respectively) can be continuous or stopped at any time during the separation step in order to increase the efficiency of the process.

6 ANALYTICAL AND PHYSICAL PARAMETERS OF PERVAPORATION

6.1 Sensitivity

The sensitivity of a method involving pervaporation basically depends on the efficiency of the separation step. In order to fit the signal provided by the analyte to the linear portion of the calibration curve of a given method, the efficiency of the mass transfer through the membrane can be manipulated thus avoiding either a dilution or a preconcentration step.

6.1.1 Efficiency of Pervaporation

The efficiency of a given pervaporation process must be evaluated in order to act on the overall system so as either to boost or to decrease the mass transfer to the acceptor chamber if required. This evaluation can be done either in relative terms by comparing the signal provided under different working conditions by the analyte (or its reaction product), previously collected in the upper chamber and driven to the detector, or in absolute terms by comparing the signal obtained under the working conditions with that corresponding to 100% mass transfer.

The relative procedure is used in optimization experiments in order to maximize sensitivity, which depends not only on mass transfer, but also on the best conditions of the derivatization reactions (prior and/or subsequent to pervaporation) and on dispersion along the continuous system, among others. No especial alteration of the
of the concentration. Point) rather than their heights, which are representative of monitored species which has passed by the detection transient signals (representative of the total amount so the two must be compared in terms of the areas of by the monitored species in the two channels is different, that in the sample. Note that the dispersion undergone analyte transferred in the separation process relative to the optimization process.

The absolute procedure requires an auxiliary channel in the upper subsystem, through which the acceptor solution is also passed, furnished with an auxiliary injection valve (AIV in Figure 3) of the same characteristics as the main injection valve (MIV) that is used to inject the sample for analyte separation and monitoring. Two sequential sample injections (the sequence is unimportant) from both valves are needed to evaluate the efficiency of the mass-transfer process. First, a volume of sample containing a given analyte concentration is injected via MIV; the analyte evaporates to the air gap, diffuses through the membrane, is absorbed by the acceptor stream, and is driven to the detector. The signal produced is proportional to the amount of analyte transferred from the donor to the acceptor stream. Second, an identical volume of the same sample is then injected through AIV and driven to the detector. A signal corresponding to the whole amount of injected analyte is obtained. The comparison of the two signals provides the amount of analyte transferred in the separation process relative to that in the sample. Note that the dispersion undergone by the monitored species in the two channels is different, so the two must be compared in terms of the areas of the transient signals (representative of the total amount of monitored species which has passed by the detection point) rather than their heights, which are representative of the concentration. 

6.1.2 Adjusting the Pervaporation Efficiency

Most often, improved efficiency is the aim of optimizing a method in order both to lower the determination limit and to obtain a steeper slope for the calibration curve. When the concentration of the target analyte in the sample varies widely, a real or pseudo dilution step is mandatory in order to fit the concentration of the analyte in some samples to the linear range of the calibration curve.

6.1.2.1 Increasing the Pervaporation Efficiency

Some ways of increasing mass transfer across the membrane are obvious and can be inferred from the nature of the separation process; others, however, are sophisticated or ingenious approaches. An increase in temperature in the donor solution increases the vapor pressure of the analyte in the donor chamber and boosts mass transfer across the membrane. The usual way of heating this chamber is by plunging it into a water bath; however, when pervaporation is assisted by microwaves focused on the donor chamber, higher temperatures can be reached with closer control. An increase in the sample volume also increases the amount of volatile species in the donor chamber in the stopped-flow mode, or prolongs the time during which the sample passes through the chamber in the continuous dynamic mode, which results in increased amounts of volatiles crossing the membrane. A continuous sample introduction mode is the best approach to increase sensitivity. The best way of increasing sensitivity by avoiding dispersion when the sample is scarce and the continuous sample introduction mode cannot be implemented is using a combined discontinuous/continuous manifold (similar to that used for solid samples, Figure 2b), suppressing the dynamic lower subsystem and introducing the sample into the donor chamber by injection. The pore size of the membrane can also facilitate passage through it, thus improving efficiency. Magnetic stirring facilitates removal of gases from the donor solution, thus accelerating attainment of the separation equilibrium. Ultrasound has a similar but greater effect than magnetic stirring; however, it favors leakage and hence losses of the gas phase. The presence of chemically inert beads of a suitable size in the donor chamber of a dynamic system boosts the transfer of volatile organic compounds (VOCs) to the air gap by delayed passage of the solution through the tortuous way formed by the beads.

One other way of enhancing the efficiency of a pervaporation process is by increasing the pressure in the donor chamber. The additional pressure must not be imposed by a stream of external, inert gas as this creates an overpressure under the donor solution which totally or partially hinders evaporation. The best way of creating overpressure in this chamber and thus improving evaporation is by lengthening the waste line.
This overpressure both forces mass transfer through the membrane and reduces the air gap over the sample, thus decreasing the amount of evaparate analyte necessary for establishment of the equilibrium in the gas phase which results in a faster mass transfer through the membrane. Thus, the efficiency obtained by using a waste tube of 280 cm rather than one of 27 cm (both of the same inner diameter) is 14 times higher.

Halting the flow as a means of improving the pervaporation efficiency can be done in one or both chambers of the separation module. Halting the flow in the donor chamber only increases the efficiency when the sample is injected since equilibrium or a near-equilibrium state is obtained in this way. In the continuous sample introduction mode, stopping the flow impoverishes the sample solution in volatiles and leads to a poorer equilibrium state in the evaporation step. The most effective halting procedure is that involving the acceptor stream as this allows equilibrium or the closest to equilibrium situation to be reached. There are two ways of implementing this step. The first is by stopping the propulsion unit for this stream. This mode makes mandatory the use of separate propulsion units for the lower and upper streams (usually the units can propel four or more channels at once) and disturbs the detector baseline through the start-and-stop sequence. Both shortcomings are avoided by the second mode, which uses an injection valve in whose loop the upper chamber of the separation module is accommodated (Figure 4a). In the filling position, the acceptor solution in the loop remains static while the solution stream passes through the bypass to the detector at the established flow rate. After the preconcentration time has elapsed, the valve is switched to the load position and the stream passed through the loop to drive its contents to the detector. In this way, a situation as close to the mass-transfer equilibrium as required can be achieved without disturbing the detector baseline.

A more efficient way of favoring mass transfer by displacing the equilibrium between the phases involved is by continuous removal of the transferred species from the upper chamber, followed by concentration, either in a minicolumn prior to the detection point or in the flow cell itself. (a) A minicolumn packed with an ion-exchange sorbent can be placed between the pervaporation module and the detector, either in the transport tubing or, better, in the loop of an injection valve (Figure 4b). The latter approach allows the retention and elution steps to take place in opposite directions in the column, thus avoiding a gradual increase in compactness that, in addition, increases pressure in the dynamic system. (b) Retention of the pervaporated species in the detection zone allows the integration of these two steps and hence monitoring the kinetics of the separation process since the volatile species reaches the detector at the same rate as it crosses the membrane (Figure 4c). Obviously, this approach can only be implemented when the detector used is nondestructive. Both approaches allow fresh portions of the acceptor solution to be in contact with the membrane in such a way that equilibrium of the separation process is never reached.

6.1.2.2 Decreasing the Pervaporation Efficiency

When the concentrations of the target analytes in the sample are higher than the upper limit of the linear range
of the calibration curve, a dilution or pseudodilution step is mandatory in order to fit the unknown concentration to this portion of the calibration curve, and hence increase the precision of measurements. In addition to the usual prior dilution of the sample or the weighing of a smaller amount, various strategies can be used to avoid the errors involved in the dilution step and in the weighing of small amounts of a solid. Such strategies include the following: (a) use of a lower pervaporation temperature; (b) changing the chemical conditions to a less favorable situation if a derivatization reaction is involved, in order to reduce the yield of the volatile or monitored species (reaction prior or subsequent to pervaporation, respectively); (c) expanding the air gap between the donor liquid level and the membrane by intercalating as many spacers as required; (d) use of a thicker membrane; (e) use of a smaller loop for the injection valve if the sample is liquid; and (f) use of a higher flow rate of the donor and/or acceptor stream.

### 6.2 Selectivity

The fact that the pervaporation separation process can only be applied to the determination of volatile analytes could be considered as a shortcoming of the technique but, at the same time, this increases the selectivity of the analyte of interest, and allows its analysis in “dirty” samples, such as biological or environmental samples, without any previous treatment, using the pervaporation as a cleanup step. If the analyte of interest is not volatile, but it can be transformed into a volatile compound by means of a selective (bio)chemical reaction, it can also be analyzed by pervaporation. The formation of the volatile analyte is done by the addition of the appropriate reagent to the sample, either continuously or by direct injection into the matrix. In any case, a derivatization reaction is often required for the formation of the species to be finally detected. The possibility of employing the derivatization reaction prior to or after the separation step broadens the application field of the technique to a variety of analytes and, at the same time, permits the coupling of the unit to several types of detectors. Pervaporation can also be applied in specie analysis, selectively analyzing the different forms of an analyte of interest (see section 7.6).

In the case of multiedeterminations and when the target volatile analytes have different boiling points, they can be selectively separated by subjecting the unit to different temperatures. In this case, a heating system allowing reproducible control of time and temperature is mandatory.

Discrimination between polar and nonpolar volatile analytes can also be achieved by using microwave irradiation of the lower chamber, so as to favor the evaporation of the polar species. The evaporation of the nonpolar compounds can then be done by conventional heating.

Selectivity can also be increased by changing the membrane used in the separation process. In general, permeability in glassy polymers is lower than in rubbery polymers and selectivity is primarily determined by the molecular dimensions of the permeating species. In recent work, three PTFE membranes with pore sizes of 0.5, 2.0, and 5.0 μm and thicknesses of 0.16, 0.18, and 0.20 mm, respectively, were compared with respect to permeability to hydrogen cyanide. The membrane with a 2.0 μm pore size and 0.18 mm thickness gave the highest permeability. The 5.0 μm pore size was supposed to give the best permeability, but the larger pore size of the membrane only allows better diffusion of larger molecular gases, and not of the small molecular gases as HCN. In such cases other considerations, such as the thickness and the pore density of the membrane, should be taken into account. The thickness is inversely proportional to the permeability whereas the pore density is proportional to it. It is expected that a larger pore size will require a lower pore density to ensure acceptable mechanical stability of the membrane. This means that the overall area of the pores through which gas diffusion takes place could even decrease with increasing pore size and hence give lower permeability.

### 6.3 Precision

The donor chamber of the unit depicted in Figure 1 was found to give rise to increasingly less reproducible signals with successive injections owing to nonhomogeneous, irreproducible dispersion. In order to circumvent this shortcoming, magnetic stirring and packing the chamber with glass beads were tried. Improved precision, expressed as relative standard deviation (RSD), was obtained in both cases, especially with the latter method (RSD = 11.29% without glass beads or magnetic stirrer, 0.79% with glass beads, and 1.87% with a magnetic stirrer).

Repeatability can also be improved by aspirating the detector waste at a flow rate equal to that of the acceptor stream or, if a chemical reaction with an additional reagent is involved, to the sum of the individual flow rates.

When the concentrations of the analytes to be determined are relatively low, a low precision is obtained, which can be attributed to the fact that equilibrium conditions in the gas phase in the donor chamber are not readily reached. This problem can be overcome by previously saturating the air gap with the volatile species, i.e. by injecting the required volume of a standard solution containing an appropriate volatile concentration and driving it to the lower part of the separation module.
The flows of both the donor and the acceptor stream are then stopped for a certain interval and, once resumed, the experiment can be continued with fairly good results (the precision thus obtained in the determination of sulfide was 5.46% as RSD). The use of long waste tubes in the lower part of the pervaporation cell can also improve the precision of a method since the pressure in the module is thus increased and small variations of pressure caused by both internal and external noise yield a smaller overall effect. In this way, for injection of the sample, the RSD decreased from 5.46 to 2.86%; for continuous sample introduction, it decreased from 7.03 to 1.61%. Halting the flows of both the acceptor and donor streams resulted in a repeatability of 2.51% at the normal waste tube length (27 cm), and 1.21% for a longer length.

The use of gas-diffusion membranes instead of ultrafiltration membranes can also improve the precision of the method, since these are not easily curved, a fact that could change the flux of the permeate owing to both an irreproducible membrane area and an increased volume of the upper chamber.

6.4 Physical Parameters of Analytical Pervaporation: Kinetics of the Mass-transfer Process

Monitoring of the mass-transfer kinetics is of paramount importance in optimization studies in order both to elucidate the factors that influence the process and to establish the appropriate pervaporation time in order to achieve a high sample frequency with minimal detriment to the sensitivity of the method. There are two ways of monitoring the kinetics of the pervaporation process: (a) by integrating pervaporation and detection and (b) by integrating a retention step with detection, after pervaporation.

Continuous monitoring of the mass transfer across the membrane can be accomplished by placing the active surface of a sensor opposite the membrane, as shown in Figure 5(a). In this way, a rising signal is obtained that reflects the enrichment of the static acceptor stream with the pervaporated species. The signal evolves to a plateau when the partitioning equilibrium of the analyte between the donor liquid–air gap–acceptor solution is reached. Electroanalytical probes (potentiometric, voltammetric, or amperometric) and fiber-optic-assisted probes have been used in this context. Optical fibers can also be used for monitoring color changes or luminescence emission.

A flow cell packed with a suitable support (ion exchanger, sorption material, etc.) can be accommodated in a nondestructive detector for continuous retention of the pervaporated species or its reaction product (Figure 5b). In this way, the content of the upper chamber is continuously removed and driven to the detector, and the fresh acceptor stream that reaches the chamber displaces the mass-transfer equilibrium, thus increasing the efficiency of the pervaporation process. A rising recording is obtained, the slope of which evolves to a plateau but never becomes flat since the concentration of volatile species in the lower chamber becomes increasingly lower, but is never zero. After the measurement period, the duration of which depends on the quantitiveness to be achieved, has elapsed, a switching valve (SV) located prior to the detector allows the acceptor stream to be replaced with an eluting solution that removes the retained species and drives them to waste. On switching the valve again, the flow of the acceptor solution through the detector is restarted, the baseline re-established and the system made ready for a fresh sample.

7 SCOPE OF ANALYTICAL CONTINUOUS PERVAPORATION

Table 1 summarizes the applications of analytical continuous pervaporation reported so far. Applications can be classified according with the nature of the sample or whether a derivatization reaction is involved in the overall process. When a reaction is involved, it can take place prior to the separation step in order to convert the target analyte into a volatile compound, or subsequent to the mass-transfer step (in the upper subsystem) in order to obtain a product measurable by the detector. The target reaction can be of chemical or biochemical nature. One other possible classification is according to whether a single or multiple parameters are determined.

The availability of multidetermination can be based on the separation process (different temperatures for analytes with different vapor pressures), on a reaction prior or subsequent to pervaporation, on a discriminating separation technique, or on the characteristics of the detector. Whether the separation step is integrated with detection also gives rise to two different types of methods. Finally, other applications of pervaporation such as speciation studies and continuous monitoring of evolving systems, as alternatives to headspace methods, etc. are also commented on below.

7.1 Types of Samples

Two broad categories can be established according to the state of aggregation of the target sample (solid or liquid). As was noted in section 5, both the manifold used and the way of introduction of the sample are different, depending on the type of sample (Figures 2a and b). The most significant difference between the treatment of liquid and solid samples is that with the former, the overall process from sample injection to delivery of the results can be fully automated. In contrast, some human intervention is required in sample weighing and fastening of the pervaporation module for solid samples. Partial automation can be achieved in this case as the rest of the process (derivatization (if required), pervaporation, transport to the detector, monitoring and data acquisition and processing, and delivery of the results) can be performed in an automated way.

7.2 Derivatization Reactions

When a derivatization reaction is developed in any of the subsystems (in the lower one to form a volatile product or in the upper one to adapt the monitored product to the detector characteristics), additional channels must be connected to the main lines in order to ensure optimal development of the target reaction. Solid reagents, the more usual situation in enzyme-catalyzed reactions, are packed in a tube (solid reactor), placed between the injection valve and the separation module when the analyte is nonvolatile in order to obtain a volatile product amenable to separation; however, the solid material containing the biocatalyst can also be placed in the donor chamber for two chief purposes: (a) to increase the yield of the biocatalyzed reaction (as the volatile product is removed from the solution into the air gap and then into the acceptor stream, the reaction equilibrium is gradually displaced to quantitativeness) and (b) to avoid dispersion of the sample in the carrier solution when the analyte concentration is low and the sample scarce (inadequate for implementing the continuous sample-introduction mode). When the purpose of the biocatalyzed reaction is to obtain a product amenable to detection, the reactor, packed with the support–enzyme conjugate, is placed between the acceptor chamber and the detector. The enzyme has also been immobilized in the upper chamber of the pervaporation module, thus integrating separation and enzymatic reaction with immobilized biocatalyst. This method has been applied to the monitoring of ethanol production during wine fermentation processes, providing longer use of the immobilized biocatalyst.

Figure 6 illustrates all these possibilities.

7.3 Individual Determinations

The simplest use of an FI pervaporation approach is for the separation/determination of a single analyte; thus, most of the methods proposed so far involve individual determinations. The determination of acetaldehyde in semisolid and solid food samples is an example of a single analyte determination, in which important sample preparation steps, such as filtration, removal of existing dyestuffs and turbidity from Carrez solution, or centrifugation are avoided. Another example is the determination of trimethylamine (an objective parameter for fish quality evaluation, correlating well with organoleptic estimation). The method is based on pervaporation of the analyte and monitoring the color change of bromothymol blue caused by the basic character of the amine, obtaining results in good agreement with those provided by the official method.

7.4 Multideterminations

Multideterminations can also rely on the manipulation of parts or parameters affecting the overall approach. One of the common ways of determining two analytes is by sequential formation of volatile compounds. Thus,
the determination of ammonium and urea in serum and urine is accomplished in a manifold such as that shown in Figure 7. Ammonium is determined by injecting the sample through valve IV1 into a basic stream that converts the ammonium into ammonia, which is removed from the donor stream and driven to the potentiometric sensor by the acceptor carrier. For the determination of urea, the sample is injected via IV2, passes through a glutamate dehydrogenase reactor (ER1) to remove the endogenous ammonium and then through a urease reactor (ER2) that converts urea into ammonia and carbon dioxide. The latter is transformed into nonvolatile HCO$_3^-$, while the NH$_3$ is pervaporated and detected. The same analytes were determined in a sequential speciation analysis of nitrogen in soil. Ammonium is first converted into volatile ammonia, which is removed by pervaporation and detected by an ammonium-ion-selective electrode located on the top of the separation unit (thus, separation and detection are integrated). Urea is converted to ammonia by reaction with dissolved urease and detected in the same way.

A reaction subsequent to pervaporation allows two volatile analytes to be discriminated. Such is the case with CO$_2$ and SO$_2$, which are removed by pervaporation under similar working conditions; the contribution of both to the pH change of the acceptor stream is monitored potentiometrically and then the well-known $p$-rosaniline–formaldehyde reaction with SO$_2$ yields a colored product that is measured photometrically. The concentration of CO$_2$ is calculated by difference between the results provided by the two detectors.

Change of temperature during the pervaporation process is another way of accomplishing multideterminations. The best way of producing fast, reproducible changes in the temperature of the lower chamber of a pervaporator is by equipping the module with a focused microwave device. In this way, speciation of mercury in a solid matrix (certified reference material (CRM)) is carried out with subsequent monitoring of the target compounds by atomic fluorescence spectroscopy (AFS).

Multidetermination capabilities can be provided by a high discrimination separation technique implemented after the pervaporator. The separation technique can be selected according to both the number of analytes to be determined and their similarities. A GC connected to a pervaporator furnished with a Tenax minicolumn as interface is used for preconcentration of VOCs before their separation and electron capture detection (ECD).

Two serially arranged detectors also permit the determination of two analytes, as noted before for CO$_2$ and SO$_2$ (potentiometric–spectrophotometric assembly). A method for the simultaneous determination of chemical oxygen demand (COD) and inorganic carbon by spectrophotometric and potentiometric detection, respectively, has been also proposed, the detectors being arranged in parallel. The carbon dioxide is removed by pervaporation and accepted in the upper part of the separation unit by a buffer stream, the pH change of which is measured by a pH electrode situated on the top of the unit. The donor stream is, at the same time, led to a spectrophotometer for the measurement of COD. The
inorganic carbon is calculated as the difference between the total concentration of CO₂ monitored potentiometrically and the COD monitored photometrically.¹¹

### 7.5 Pervaporation as an Alternative to Headspace Methods

One of the most promising uses of pervaporation is as an alternative to headspace methods. Two methods of this type have so far been proposed for mercury speciation and for VOCs in solid samples; both testify to the advantage of pervaporation over headspace methodology. Both use the overall assembly shown in Figure 8, by which the analytical process is developed in four steps. (1) **Pervaporation of the analytes**. About 0.5 g of sample is placed in the donor chamber of the pervaporation cell. The cell is then closed, connected to the system and placed either in a water bath or in the vessel of a focused microwave device, depending on the polar or nonpolar nature of the target analytes, which evaporate into the gas layer above the sample and then diffuse through the membrane to the argon acceptor stream. (2) **Preconcentration/desorption**. A minicolumn of Tenax, positioned in the loop of an injection valve that is placed in an ice bath, is used to preconcentrate the volatile species that pass through the membrane of the pervaporation unit. In order to desorb the retained species and inject them onto the chromatographic column, the flow of Ar from the pervaporation unit is diverted so that the valve loop is shut off with no gas flow passing through it. The Tenax minicolumn is removed from the ice bath and placed in a muffle oven at a suitable temperature for nonpolar analytes or in a microwave device for polar analytes, following which the valve is switched to the “inject” position to allow a He flow to pass through the column and flush the desorbed species from the loop of the injection valve through the connector between the injection valve and the chromatograph, and onto the chromatographic column. (3) **Chromatographic separation**. The He stream containing the desorbed compounds enters the injector in a continuous manner via a hypodermic needle fixed to the injector inlet. This is then mixed with an additional stream that flows through the normal carrier gas inlet into the injector. The chromatograph oven is programmed as required and the species are separated. (4) **Detection of the separated species**. As the individual mercury species emerge from the column, they are passed through a pyrolysis unit set at 800°C in order to break the compounds down to elemental mercury. This stream is then mixed with a make-up gas on its way to the detector. A second stream of the same gas (Ar) is used as sheath gas, which increases the reproducibility as a result of the He/Ar/Hg flow to be maintained in the beam of the atomic fluorescence detector. VOCs require no pyrolysis unit, so the separated analytes are driven directly to the ECD unit. Hydrophilic membranes could not be used in these studies, as they permitted the passage of water-vapor through them, which, as a result, was led to the GC column. Therefore, PTFE hydrophobic membranes were used, as they provided better sensitivity and higher thermal stability than other hydrophilic membranes, such as the PVDF type.¹²

The advantages of pervaporation over headspace methodology are as follows: (a) the thin air-gap layer above the sample uses very small amounts of analytes to establish equilibrium with the solid or liquid phase and mass transfer across the membrane; (b) continuous removal of the volatilized analytes across the membrane from the air gap displaces the mass-transfer equilibrium and increases the efficiency of the separation process; (c) continuous removal of the pervaporated analytes to the preconcentration column allows fresh portions of acceptor gas to come continuously into contact with the diffused species, thus displacing the mass-transfer equilibrium; (d) the separation process can readily be automated for laboratory use; and (e) there is no need for a water-vapor condenser, as in the case of the “purge and trap” mode, or a hydrophobic sorbent, since no water crosses through the hydrophobic membrane.

#### 7.6 Speciation Studies

When a pervaporation module is used as a fundamental device in speciation analysis, this goal can be achieved in the following ways.³³

First, (bio)chemical treatment can be applied as a previous discriminating reaction. Hence, it can favor the

Papaefstathiou, M.D. Luque de Castro, ‘Integrated Pervaporation/Detection: Continuous and Discontinuous Approaches for the Treatment/Determination of Fluoride in Liquid and Solid Samples’, *Anal. Chem.*, 1995, 67, 3916–3921.)
formation of a volatile compound from one of the forms of the analyte of interest, thus permitting the simultaneous determination of volatile and nonvolatile compounds by monitoring both the acceptor and the donor streams, as in the method proposed for the determination of COD and inorganic carbon by spectrophotometric and integrated potentiometric detection, previously commented upon. A similar method has also been applied to the determination of total and free SO$_2$ in wine. The sulfur dioxide formed in an acidic stream is removed from the liquid sample and collected in an acceptor solution containing p-rosaniline and formaldehyde, the colored compound formed being monitored photometrically. (Bio)chemical treatment can also be applied in samples containing both a volatile and non-volatile form of the analyte, promoting the conversion of the nonvolatile form into the volatile form. This is the case in the sequential determination of ammonia and urea in biological fluids, making use of immobilized enzymes and a pervaporator coupled to an FI manifold, commented upon in a previous section.

In other cases, the analytes to be determined are both involved in (bio)chemical reactions in order to yield volatile compounds. One example is the speciation of mercury in solid samples making use of microwave-assisted pervaporation/atomic fluorescence detection in a continuous-flow system. A focused microwave device has proved highly efficient when the analytes are sufficiently polar to interact with microwave energy [e.g. Hg(NO$_3$) and PhHgOAc]. As can be seen in Figure 9, the experimental set-up required is very simple. In this manifold, the sample is weighed in the donor chamber of the pervaporation cell and the cell is tightly closed and connected to the loop of the injection valve, which acts as a SV. This allows the carrier stream (water or argon) to pass either through the acceptor (upper) chamber of the pervaporation unit and then into the detector, or via a bypass to the detector while the flow in the pervaporation cell is stopped. Although the flow through the pervaporator is stopped, the baseline does not change because the carrier stream proceeds to the gas–liquid separator via the bypass loop at the same rate as it circulates through the pervaporation cell. Once the sample is in the donor chamber, the reagents are injected via one of the inlets of the pervaporation cell. Septa similar to those used in GCs allow the syringe needle to penetrate the donor chamber, inject the reagents and be removed with no loss of either sample or reagents. One minute after the reagent is injected, the microwave device is switched on at a preset power for a given time, after which the cell is allowed to cool for 1 min before the SV is activated to divert the carrier through the acceptor chamber of the cell, collecting one of the mercury compounds to the gas–liquid separator if the acceptor carrier is a liquid, or directly to the atomic fluorescence detector if the carrier is gaseous. When the detector baseline is restored, the valve is switched again to isolate the pervaporator and the microwave digestor is switched on again for another preset time and at a suitable power setting for the other mercury compound. After the pertinent peak has been obtained, the valve is switched to isolate the cell and the system is thus made ready for the next sample.

Second, the temperature of the donor chamber can be changed according to the vapor pressure of the target compounds. Exact control of temperature is then required, as was commented upon previously.

Third, the pervaporator can be connected to high-discrimination separation equipment such as a GC, as described in the previous section.

### 7.7 Integrated Pervaporation/Detection

The best way of monitoring the kinetics of pervaporation is by inserting a probe-type sensor in the acceptor chamber, with its active surface faced to the membrane. A number of methods based on this principle have been developed. The determination of fluoride in liquid (ceramic industry wastewater, dissolved fertilizers) and solid samples such as tree leaves by formation of a volatile product with hexamethyldisiloxane using manifolds such as that shown in Figure 10 is an excellent example of this approach. The most outstanding advantages derived from integrating pervaporation and detection are as follows: (1) the response time is shortened relative to the conventional location of the sensor after the separation module since transport of the target species from the separation module to the detector is avoided; (2) the kinetics of mass transfer across the membrane can be monitored, which affords a better understanding of the separation step and easier, in-depth optimization; and (3) the set-up required for the determination of a volatile analyte or reaction product in solid samples can be miniaturized by integrating the leaching, derivatization, separation, and detection steps.

---

Papaefstathiou, ‘Analytical Pervaporation: a New Separation Technique’, *Trends Anal. Chem.*, 17, 41–49. Copyright (1997) with permission from Elsevier Science.)
7.8 Types of Detectors

Any type of detector, whether molecular or atomic, can be coupled to a pervaporator through an appropriate interface such as a transport tube, a microcolumn packed with adsorptive or ion-exchange material, or a gas–liquid separator. The acceptor carrier stream can be either liquid or gaseous depending on the characteristics of the detector. The detectors often used in conjunction with pervaporation are of the spectroscopic [atomic (fluorimetric) or molecular (photometric, fluorimetric)], electroanalytical (potentiometric, voltammetric, or amperometric), electron-capture and flame ionization types. The low selectivity of some detection techniques such as photometry, ion-selective electrode-based potentiometry, and flame ionization, is countered by that of the pervaporation step, which endows the overall analytical process with the selectivity required to process highly complex matrices.

7.9 Pervaporation as an Interface Between Evolving Systems and Monitoring

The fact that the presence of solid material, suspended particles, macromolecules, etc. does not disturb the pervaporation process, and hence the passage of the volatile compounds into the acceptor stream is independent of the state of aggregation, is of great interest. Fermentation processes, environmental systems, and, in general, any evolving process that must be continuously or intermittently monitored are potential candidates for implementation of pervaporation-assisted monitoring. The presence of colloidal particles, macromolecules, etc. in fermenters calls for the use of filters of different nature and pore size in order to ensure cleanliness of the sample prior to its insertion into the analyzer. This step dramatically complicates the overall set-up and can even hinder full automation or make it expensive. In addition, a separation module such as a dialyzer or gas diffuser may be necessary for subsequent separation of the target analyte from the rest of the matrix. The use of a pervaporator as an interface between fermenters and monitoring devices (which can be extended to other evolving systems) has proved a suitable means for avoiding the cleanup step (provided the analytes are volatile or can be converted into volatile compounds, which is very often the case in fermentation processes). The only requirement for using a pervaporator as an interface between the evolving system and the monitoring device is that the transport tube and the inlet/outlet of the separation module should be of appropriate diameters, which will be a function of those of the particles in the stream. Stirring of the donor chamber avoids sedimentation in the bottom, which can be facilitated by aspirating the donor waste. When the system evolves slowly and continuous monitoring is unnecessary, a modified injection valve (also of an appropriate loop diameter and sample path) can be a more effective choice. The injection mode is known to improve continuous monitoring in that the baseline is restored after each transient signal. As a result, any changes in the baseline due to detector problems (e.g. fouling of the flow cell), are immediately detected as such; on the other hand, such changes during continuous monitoring are taken to be changes in the evolving system. This fact, which does not pertain to pervaporation, but to continuous-flow systems, must be taken into account in choosing continuous or discontinuous monitoring.
8 PROSPECTS FOR PERVERAPORATION

Pervaporation is a useful tool in the analytical laboratory, and is characterized by simplicity, ease of automation, and the possibility of miniaturization. The potential of pervaporation for the pretreatment of liquid or solid samples can be inferred from both the intrinsic features of the technique and existing methods using a pervaporator, two subject matters of this article. The most interesting applications of analytical pervaporation developed so far are: as an alternative to gas diffusion, its use with liquid samples containing solids in suspension or of a corrosive nature, its use with solid samples for the determination of a single analyte or multideterminations, integrated pervaporation—detection, and coupling of a pervaporator to a GC, as an alternative to headspace sampling.

Consolidation of this technique as an effective analytical tool relies on two previous, sequential developments: (a) the availability of sufficient research experience on the subject to compile a cook-book of methods where potential users can search for solutions for specific problems and (b) the commercialization of precise, inexpensive pervaporation modules meeting the requirements of a variety of samples and analytes. The development of the methods and the theoretical studies on pervaporation should permit the consolidation of the technique as an effective analytical tool in routine analysis that can be applied in various fields, including environmental, clinical, food, and industrial chemistry.

Phenolic compounds are widely distributed in our ecosystems. In addition to naturally occurring phenols, the majority of toxic phenolic substances are released into the environment by industry and agriculture. As the manufacture and use of phenols requires qualitative and quantitative control, a wide variety of methods have been developed to determine phenolic compounds. In addition to coarse screening to rapidly obtain a general overview, many highly specialized techniques exist that are geared to individual analysis problems. The range of available methods extends from steam distillation and classic liquid–liquid extraction (LLE) as sample preparation combined with photometric or ultraviolet (UV) detection, to more sophisticated techniques such as liquid–solid extraction (LSE) including solid-phase extraction (SPE) and solid-phase microextraction (SPME) coupled to gas chromatography/mass spectrometry (GC/MS) and high-performance liquid chromatography/mass spectrometry (HPLC/MS). This article describes the most suitable methods, taking account of special factors such as substance class, chemical properties, concentration range and accompanying matrices. Some new trends in phenol determination are also discussed in comparison with the established methods. The basic factors governing the selection of suitable analysis methods are also covered.

1 INTRODUCTION

The class of hydroxylated aromatic compounds known as the phenols is widely distributed in the natural environment. A great variety of phenolic compounds are also released into the environment as a result of human activity. In particular, chlorinated, long-chain alkylated, nitrated and sulfonated phenols contribute to the dangerous pollution of surface water and groundwater.

Owing to their toxicological effects and their partial persistence in both the environment and in biological systems, contamination by phenolics must be subjected to environmental monitoring. As a result of their wide range of physicochemical and biological properties, phenolic substances are ubiquitously distributed. Being naturally occurring organic substances, efficient biological degradation pathways exist for phenols. For example, phenol oxidases convert phenols to corresponding chinones, which act as radical traps. Furthermore, phenols are typical metabolites of oxidative transformation processes of aromatics. Their high reactivity enables the easy formation of, for example, nitro-, halogeno-, and sulfonic phenols, and also supports rapid degradation reactions.

1.1 Occurrence of Phenolic Compounds and their Penetration of the Environment

Phenols are widespread in nature as constituents of plant dyestuffs, tanning agents, lignin, flavonoids, etheric oils, substances used as fragrance additives and flavorings, steroids, alkaloids, and natural antibiotics. Phenol is also...
produced by normal human metabolism from tyrosines and applied pharmaceuticals via areneoxides.

The bactericidal properties of phenol make it a useful substance in natural defense mechanisms for biological systems, resulting in its application as a disinfectant. In 1865, a 5% phenol solution (also known as carbol or carbolic acid) was introduced as a disinfectant in surgery, and for a long time remained virtually the only antiseptic available. However, these properties are no longer of such interest, and its usage as a disinfectant has declined. Nevertheless, the use of phenol in cosmetics is still permitted when the relevant restrictions are observed.(2)

Nowadays, phenol is much more attractive as an educt for technical products such as phenol-based resins, ε-caprolactam, bisphenol A, adipic acid, alkylated phenols, aniline, chlorophenols, plasticizers and antioxidants.

Phenol used to be produced from coal tar, a ton of which contains around 250 g of phenol as a decomposition product of fossilized oxygen-containing plant constituents. Hence, much of today's environmental pollution attributed to phenolic compounds stems from recent manufacturing processes involving lignite and derived products. Every year thousands of tons of phenol alone (5174 kt in 1985)(3) are produced by splitting cumol-hydroperoxide.

Environmental problems caused by phenolic compounds are attributable to their long-term, large-scale uncontrolled release, as well as their persistence and, above all, their toxicity (especially halogenated phenols).

The toxicities of individual phenols vary depending on the type, number and position of the substituents. They can be estimated via their lipophilicity, which can be determined using reversed-phase chromatography.

In human exposure studies, phenol itself is rapidly absorbed into the body via ingestion, skin absorption or inhalation, and rapidly excreted.(4)

Exposure to phenol vapor may cause severe irritation, neurosis, affect the central nervous system, and damage the liver and kidneys. However, there is a lack of exposure data on chronic effects in humans. As evidence of the carcinogenicity of phenol in humans is inadequate, it is not classifiable in this regard.(5)

Even a few types of halogenosubstituted phenols occur naturally, as the isolation of bromophenol from marine organisms has demonstrated. However, the majority of halogenophenols are of anthropogenic origin, such as from wood processing and preservation plants, kraft pulp mills, pesticide manufacturing, and formulation plants. A typical representative is pentachlorophenol (PCP), which is used as an insecticide and a fungicide to protect timber from fungal rot and wood-boring insects, and which is also applied as a biocide in industrial water systems. The by-products of technical grade PCP, such as polychlorodibenzop-dioxins and hexachlorobenzene, intensify the environmental pollution problems many times over.

The discovery of these highly toxic by-products was yet another reason for the use of PCP being phased out. Other reasons include the toxicological and ecological effects of PCP.

1.2 Properties and Toxicological Importance of Selected Phenols

PCP is rapidly absorbed through the gastrointestinal tract following ingestion. It is known to be extremely toxic to humans because it affects the circulatory system and is accompanied by heart failure. Accumulation can occur in the liver, kidneys, plasma protein, brain, spleen, and fat.(6) It is eliminated and excreted unaltered or in conjugated form via the urine. The United States Environmental Protection Agency (USEPA) estimates that the consumption of 0.03 mg kg\(^{-1}\) per day (reference dose) of PCP over a lifetime is unlikely to result in the occurrence of chronic effects.(7)

PCP may be highly toxic to plants(8) and to many species of fish; for example, LD\(_{50}\) = 52 µg L\(^{-1}\) for rainbow trout. The high bioaccumulation factors caused by the lipophilicity of PCP lead to extremely high levels in several species of fish, invertebrates and algae that are significantly higher (up to 10,000 times) than the concentration in the surrounding waters.(6)

In soil, PCP is moderately persistent with a reported field half-life of 45 days.(9) The sorption of PCP is strongly dependent on the pH conditions of the surrounding medium and increases with higher proportions of organic matter. Under neutral or alkaline conditions, PCP is poorly adsorbed and is mobile in many soils.(9)

In the aquatic environment, PCP is mainly bound to sediments and suspended particles,(10) often hampering analytical determination.

Some phenols are used for munitions manufacturing, handling and disposal, causing the uncontrolled input of (initially) nitrophenols into the soil. During their transformation into the corresponding aminophenols, the toxicity changes (mostly carcinogenically) and, under unfavorable conditions, the contaminants may reach the groundwater.

Another area of research is the environmental behavior of nitrated and aminophenols, which is characterized by various negative effects on organisms. For instance, 2,4-dinitrophenol is used in the manufacture of dyes, wood preservatives, insecticides,(11) explosives, herbicides, photographic developers, picric acid and picramic acid. It is poisonous to humans by ingestion, inhalation and skin contact. It is also an experimental teratogen and mutagen, has phytotoxic effects, and harbors the danger of cumulative effects.(12) Nitrated phenols and their metabolites...
Compounds. Long-chain alkylphenol ethoxylates, and derived phenols are known to be endocrine-disrupting xenobiotics (Scheme 1).

![Scheme 1](image)

**Scheme 1** Chemical structures of endocrine-disrupting pheno
colic compounds bisphenol A and isomeric nonylphenols.

Bisphenol A is more relevant as a food contaminant because it is used as an additive in polycarbonate plastics and epoxy resins, both of which are used in food and drink packaging, as well as in lacquers to coat the inside of food cans and water supply pipes. Bisphenol A exhibits hormonal effects at a concentration level as low as 2–5 µL⁻¹. Although human exposure is more probable via the food chain, uptake from drinking water cannot be ruled out, especially if water supply devices are coated by plastics. Some greater environmental human health risks may arise from alkphenols present in surface, ground- and drinking water.

Long-chain alkylated phenols, such as nonyl- and octylphenols, are produced and released into the environment, whereas the degradation of alkylphenol ethoxylates and tris(nonylphenol phosphites) used predominantly as industrial detergents or surfactants and as antioxidants in plastics results in the release of nonylphenols. Investigations into the environmental behavior of these industrial products indicates only the partial degradation of these compounds during their passage through sewage treatment plants. The resulting metabolites (including the free phenolics) enter the aquatic environment and are persistent in rivers and adjoining groundwater, soil and sediments. High bioconcentration factors have led to the contamination of fish and birds between 10 and several thousand times higher than in the surrounding environment. Diverse nonylphenol concentrations (10 and 1500 µL⁻¹) in river water have been published. Drinking water analysis in the USA has indicated a concentration of about 1 µL⁻¹ total nonylphenol-derived compounds. Environmental interest in this class of compounds arises from its direct toxicity to organisms and the endocrine-disrupting effects determined for the nonylphenols. Biotests demonstrated them to be 10 times more toxic to fish and daphnia than the original alkylphenol ethoxylates.

Although the estrogenic (estrogen-mimicking) effects of the alkylphenols were first described in 1938, it was only in 1991 that the effects of nonylphenols on cultured human breast cells finally led to concern over health risks. Tissue concentration levels of just 0.1–1 µmol octyl- and nonylphenol affect fetal steroid synthesis and may cause masculinization, according to experiments with adult male rainbow trout. After exposure to 30 µg L⁻¹ octyl- or nonylphenol, the fish began to produce the female egg yolk protein vitellogenin. The exposure concentration used in these experiments corresponded to the amounts found in river water polluted by industrial effluents.

When the environmental concentration of alkylphenols, their high bioaccumulation factors, and their estrogenic effect levels are taken into account, it seems likely that the current amounts of alkylphenols may affect the endocrine system of some organisms. The extent to which these results can be transferred to humans is not yet clear because these effects have only been the target of scientific interest over the past few years. The data available concerning occurrence, environmental accumulation and human exposure are still few (compared for example with polyaromatic hydrocarbons), a situation exacerbated by the lack of official regulations and current analytical standard protocols for the environmental monitoring of alkylphenols. The initial consequences of the studies have been the partial or complete ban of the use of alkylphenols as cleaning agents, although they are still used in paints, pesticide formulations, and lubricants. The phase-out of mainly nonylphenols as planned by the Paris Commission is to be carried out in stages and should be complete by the end of 2004.

## 2 REGULATIONS

### 2.1 General

As population growth, urbanization and industrialization continue, the demand for water will increase further, with at least a partial depletion resulting from the nonreversible conversion of pure water to wastewater. Directives, regulations and laws for water management are therefore needed to preserve the quality of our limited water resources.

These regulations depend on the classification of waters. Although guidelines for surface water control contain priority lists of dangerous substances to be monitored and eliminated from surface waters, they do not set any maximum concentration limits. Directives concerning drinking water and surface water used for drinking purposes that establish water quality by recommended or maximum levels are more restrictive.
Since the late 1970s, increasingly stringent regulations have been established worldwide governing the production, transport, application and discharge of toxic substances, as well as the equipment at industrial and wastewater treatment plants. These regulations and the more intensive control of surface water quality have brought about a general reduction in pollution.

To preserve and maintain this encouraging development, governments are endeavoring to follow national and international trends concerning the production, usage and discharge into the environment of hazardous substances, and to revise and adapt existing regulations to actual environmental situations.

For example, in 1996 the Safe Drinking Water Act Amendment was introduced in the USA. Its purpose is to bring about substantial changes to the US national drinking water program, and to provide greater protection and public information. Several regulatory actions are included such as the Disinfectant/Disinfection By-products Rule and the Interim Enhanced Surface Water Treatment Rule, both of which address the discharge and environmental distribution of pathogens and disinfectants including chlorinated phenols. Streamlining of the environmental and health protection program is proposed in the near future, to improve its effectiveness under reduced technical and administrative conditions.

Phenols and selected alkylated, nitrated, and chlorinated phenols are included in various national lists of toxic chemicals as well as in programs that control dangerous substances discharged into the environment (e.g. USEPA in the USA, Municipal/Industrial Strategy for Abatement (MISA) Program in Canada, German National Standards Organization (DIN) in Germany, and the European Community (EC) directives).

### 2.2 Protection of Water Resources by National Programs

The current USEPA regulations are based on one of the major environmental laws of the USA, the 1977 Clean Water Act, which regulates the discharge of pollutants into water. Certain phenolics were included on the USEPA list of priority pollutants, chiefly due to their toxic properties and environmental persistence.

In every country, specific priority lists and state guidelines exist depending on the particular industrial or agricultural substructures. For example, the Canadian Ministry of Environment has serialized the analytical monitoring of nine industrial sectors discharging dangerous material into the environment. Within the framework of the MISA, the guidelines force the control of a total of 104 volatile and semivolatile organics, including the extractable phenols (MISA group 20). The attribute “extractable” indicates an LLE procedure for sample preparation.

Slightly different limits for relevant substances are often encountered when different national guidelines are compared. Within the European framework, the input of environmentally relevant substances into aquatic systems is an essential part of EC Directive 76/464/EEC. This guideline lists dangerous and persistent compounds that have to be controlled, and provides quality parameters for drinking water, surface water used for drinking purposes and secondary waters (bathing, sea and river water). The more detailed directive 75/440 lays down the maximum permissible content of total phenols (determined by steam distillation) in surface water used for drinking water production. This group-specific total concentration of phenolics should not exceed 1 or 10 µg L\(^{-1}\), depending on the water treatment techniques used. The regulation does not stipulate the determination of individual phenolics. However, judging by today’s criteria, this requirement seems to be an inadequate description of the environmental situation. The latest findings concerning the specific toxicological properties of isomeric phenolics and semivolatile phenolics, such as nonylphenols or bisphenol A, demonstrate that specific trace analysis for some individual compounds is needed.

By contrast, the World Health Organization (WHO) gives quite exact recommendations regarding, for example, the presence of PCP in drinking water, where it should not exceed a concentration of 9 µg L\(^{-1}\).

The priority pollution list of The Netherlands, updated in 1994, also laid down recommended and maximum permissible values for phenolic compounds (mostly as sum parameters). This provides a useful tool for the risk assessment of soil and groundwater contamination by toxic chemicals, although its general significance as a point of reference is waning with the introduction and increasing acceptance of EC regulations. A comprehensive review of the EC regulations concerning surface water control is given by Hennion et al. At present, although globally valid regulations such as the International Standardization Organization (ISO) norms are available, they mostly concern analytical procedures such as the determination of monovalent phenols for water quality monitoring (ISO-8165-1) by gas chromatography (GC). There are no general global regulatory restrictions limiting the concentration levels of the discharge of phenols into the environment. All we have are recommendations based on scientifically sound toxicological research results.

It is highly likely that most of the phenols enter the environment via waterways in the form of industrial or municipal wastewater. Hence, primary interest must be devoted to the occurrence of phenolic substances in aqueous systems. The standard methods currently used...
were therefore developed to determine phenols in various waters.

For example, USEPA method 604\(^{(28)}\) has been laid down for municipal and wastewater control, whereas USEPA-625\(^{(23)}\) addresses phenols such as polycyclic aromatics in wastewater. More comprehensively, the USEPA series 8000 deals with methodologies for identifying and quantifying priority organic pollution contained in the USEPA lists (Appendix VIII and IX) in groundwater, wastewater, and solid material deposited or discharged. In addition to the USEPA method 604, the list of phenols to be determined by USEPA 8040\(^{(29)}\) also includes five isomeric trichlorophenols, two more tetrachlorophenols, 2,6-dichlorophenol, all cresols, and dinoseb (2-sec-butyl-4,6-dinitrophenol). The USEPA method 8041\(^{(24)}\) includes additional phenolic substances and pesticides in line with the latest research findings regarding the toxicity and environmental behavior of phenol derivatives.

Parallel to this, the USEPA Contract Laboratory Program (CLP) features analytical methods to determine compounds of the target compound list (TCL) in groundwater, sediments and soil from refuse dumps. The protocols developed by the Environmental Monitoring Systems Laboratory in Las Vegas are based on the Superfund Amendments Reauthorization Act (February 1988 statement of work). The target analyte list of semivolatiles contains six selected phenols to be determined (Table 1).

Reference compounds for method validation and calibration are available from various manufacturers as individual components or as mixtures prepared in accordance with the corresponding target lists and official determination methods.

### 2.3 Regulations Regarding the Determination of Phenols in Solid Material

Methods describing the determination of phenolic compounds in soils, sediments and sludge are often derived from or combined with phenol determination procedures used for wastewater. The main difference is to be observed in the sample extraction procedures where

LOD, limit of detection.
LSE methods such as Soxhlet (USEPA 3540 and 3545) and sonication (USEPA 3550) are preferred for standardization. The subsequent steps of clean-up, analyte concentration, and analysis are comparable to those applied for wastewater. The problems that may appear in the analysis of suspended phenolic compounds are discussed later. Approved methods that provide conditions for phenol determination from wastewater as well as from soil and sludge include USEPA 8120, and USEPA 8040, which use the sample extraction techniques mentioned above. The achievable LOD closely depends on the sample matrix present and the method of sample preparation used. The derived practical quantification limits are geared towards the LOD values of the reference method corrected by a theoretical factor that characterizes matrix effects. For example, all LOD values listed in Table 1 (column USEPA 8040) have to be multiplied by a factor of 10 for the wastewater matrix or 10,000 for high-level soil and sludge extracted by sonication. Nevertheless, the corrected values are not always attainable if the matrix is too complex.

2.4 Recommendations for Air Monitoring

The control of air pollution by phenolic compounds is mostly limited to the working environment and indoor air monitoring, along with emissions monitoring of the volatile phenols that may, for example, be discharged during the manufacture of pesticides and phenol resins or released from furniture or wood treated with preservatives.

Methods for air monitoring (including workplace and indoor air measurements of dangerous compounds) are defined in NIOSH (National Institute for Occupational Safety and Health) and OSHA (Occupational Safety and Health Administration) protocols.

The phenols and cresols present in indoor air are determined using NIOSH 2001/OSHA 32 methods. The pollution of ambient air is monitored using the USEPA method for toxic compounds TO-8, which samples the analytes by impinger traps (72 L at a rate of 100 mL min⁻¹ for 12 h) and analyzes the phenol- and cresol-containing extracts by high-performance liquid chromatography (HPLC)/UV or electrochemical detection.

The USEPA method TO-17 determines phenol from smaller volumes (1–4 L, 16–67 mL min⁻¹) using a shorter sampling time (1 h) and thermal desorption/GC/MS for determination. The multisorbent tubes are packed with, for instance, Carbopack™ graphitized carbon black and Carboxen™-1000 type carbon molecular sieve. Other sorbent packages have been proposed for VOC (volatile organic compound) enrichment, each combined with optimum gas flows and temperatures for sorbent conditioning, air sampling, and for thermal desorption/GC/MS.

Phenylphenol, used as a germicide and fungicide on foods, has to be detected in accordance with the USEPA TO-10A method, which uses a polyurethane filter cartridge for sampling and HPLC for the analysis of this special air pollutant.

The USEPA standard methods are often used as global reference protocols and have been widely accepted in many countries for environmental analysis, allowing the global exchange of data between laboratories.

2.5 Current Analytical Methodologies

The analytical procedures of the USEPA methods developed for phenolic determination include LLE from the acidified water sample. Nearly all methods use GC coupled with various detectors such as flame ionization detection (FID), electron capture detection (ECD) and mass spectrometry (MS) for analysis.

The rapid development of analytical instrumentation has overtaken some standard techniques, such as the use of packed columns for GC separation.

However, owing to new regulatory strategies, such as those preferring environmentally friendly methodologies that reduce solvent consumption and do not use toxic chemicals, government regulation agencies have become quite flexible about accepting and introducing new analytical techniques (e.g. SPE or micro-LLE instead of LLE).

The need to use state-of-the-art methods for monitoring dangerous organic pollutants such as phenolics, halogenated compounds, polycyclic aromatic hydrocarbons, pesticides, amines, phthalates or surfactants in aquatic systems is now recognized.

Most standard procedures have been derived from methods used for drinking water. This means that the detection limits described were obtained without any clean-up, because of the lack of a matrix. If groundwater with low amounts of associated organic matter has to be analyzed, these standard methods may be easily used. However, care must be taken if these methods are to be transferred and adapted to matrix-loaded surface or wastewaters. In such cases, some preliminary sample preparation (clean-up) is needed over and above the extraction, concentration and chromatographic separation (GC or HPLC) procedures usually applied.

If a good method of optimization succeeds, i.e. high enrichment factors are attained for the target analytes, the matrix effects are eliminated by clean-up. If the chosen analysis technique is selective enough, the detection limits may be of the same order in both drinking water and surface water.

Finally, two examples of official methodologies in common usage for water monitoring are shown in Figure 1.
The LLE technique has been proposed in many official methods and is still used because of its ease of use, even though it no longer corresponds to the state of the art or the latest requirements to replace methods using large amounts of toxic solvents. The SPE and microextraction techniques should be preferred in future developments.

As analytically produced data are used as a basis for global conclusions, risk assessment and ultimately to lay down regulatory limitations for environmental pollution, the need for analytical quality control is becoming increasingly evident.

Analytical quality assurance is an additional criterion whose significance is growing in the assessment of environmental data. Only the critical validation of each individual step in sampling, sample transport, storage and preparation, analytical determination and data processing can guarantee the reliable interpretation of data.

3 DETERMINATION OF PHENOLS AS A GROUP PARAMETER

A detailed analysis of individual phenols is not always required for on-site screening and alarm monitoring. Instead, it is the ability to detect a sudden increase in the concentration of pollutants as soon as possible that is needed. The “phenol index” is a group-selective parameter that indicates the content of antipyrine dyeforming compounds by photometric detection. However, although phenols are the main target substances, interference may arise from an assortment of different compounds. In addition, the phenol index is not well designed for the determination of para-substituted phenols, thus this method can lead to underestimated results.

Based on the draft version of international norm ISO/DIS 6439, the DIN has drawn up the method DIN 38 409 H 16 to determine the phenol index in water, wastewater, and sludge.

Depending on the water quality, various procedures exist for determining the phenol index. Direct photometric determination using phenol–antipyrine dye stuffs is recommended for investigating drinking water or surface water with average pollution-containing concentrations of about 10–150 µg L⁻¹ (related to phenol). The products absorb at 460 nm and result from the oxidizing coupling of phenols with 4-aminantipyrine (4-amino-2,3-dimethyl-1-phenyl-3-pyrazoline-5-one) under alkaline conditions and in the presence of potassium peroxodisulfate. The absorption intensity of the dyestuff extracted with trichloromethane is used as a measure of quantity (standard method variant DIN 38 409 H 16-1). Some aromatic amino compounds are also able to form antipyrine products that are photometrically sensitive in
the same range as phenols. Thus interference may occur and this method is unsuitable for examining water samples containing cyanide or amino compounds.

Alternatively, a slightly different version of the sum parameter method may be applied, which excludes most of the amino compounds prior to analysis. This is achieved by adjusting the sample solution to pH 0.5, forcing the conversion of the amino compounds into salt forms. Prior to the coupling reaction, the phenols are then separated from the water by water vapor distillation (DIN 38 409 H 16-2). As the interfering components are now absent, distillation can be performed using just a small amount of acidic solution (pH 4).

At higher concentration levels (0.1–10 mg L\(^{-1}\) and above), the sample must be diluted and extraction of the resulting dyestuff is generally unnecessary. Photometric detection is performed directly on the water sample (DIN 38 409 H 16-3). The procedure is very sensitive to oxidizing compounds (chlorine), reducing substances (SO\(_2\) or NO\(_2\)\(^-\)), colored components, and cyanides. In any event, the procedure requires several chemicals and time-consuming steps.

To minimize the requirements for solvents and reagents, the entire procedure has been scaled down, and made suitable for on-site application. The cuvette test has been developed from the above-mentioned phenol index method and is divided into two categories. Phenols can be determined in concentration ranges of 0.05–5 mg L\(^{-1}\) in water, wastewater, soil and waste (LCK \(\text{SO}_2\) or NO\(_2\)\(^-\), \(\text{SO}_2\) or NO\(_2\)\(^-\), colored components, and cyanides. In any event, the procedure requires several chemicals and time-consuming steps.

4 DETERMINATION OF PHENOLS

In addition to rapid screening, mostly at higher concentration ranges, trace analyses of individual phenols are sufficient to provide an appropriate stock of data for risk assessment and environmental protection. The determination of a large variety of compounds in the low microgram per liter range requires high analytical performance and sophisticated sample preparation techniques. The development of an analytical strategy depends primarily on the nature of the accompanying matrix and on the analyte concentration.

A fundamental review of the determination of phenols in water samples has recently been published. The current methods are described as LLE and LSE, off-line and on-line, combined with GC and liquid chromatography (LC). Use of LSE with subsequent thin-layer chromatography (TLC) can provide an easy, rapid, and inexpensive route to obtaining an overview for screening purposes.

4.1 Preparation of Aqueous Samples

A concise review of the main steps and techniques for specific phenol determination is contained in Water Analysis. This booklet features practical hints, analysis flow diagrams and operating conditions, which provide a convenient introduction to the methodologies currently used.

In general, for aqueous sample preparation, LLE, LSE, SPE, and SPME are preferred in combination with GC/FID, ECD, MS and the option of prior derivatization. HPLC with UV detection does not require any additional derivatization, and is increasingly being used for phenol determination from water samples.

4.1.1 Liquid–Liquid Extraction

The classic variant of sample preparation is LLE under acidic conditions. The implementation of this method in major standard procedures accounts for its widespread use in environmental laboratories, although more recent methods are now available with a number of advantages such as simplicity, good reproducibility, and sensitivity.

USEPA standard methods 604 and 625 involve the methylene chloride extraction of water samples after acidification to pH 2. Subsequent GC analysis reaches detection limits in and slightly below the microgram per liter range (Table 1).

The analytes in surface water and wastewater are often accompanied by organic material, such as humic and fulvic acids. These matrix components may notably affect analytical performance because of their competing extraction and accumulation under acidic conditions. Therefore, in LLE the presence of interfering material probably requires additional sample clean-up.

Another important aspect concerning matrix influence is division of the pollutants between the suspended matter and the water. One argument in favor of LLE is that
contaminants are extracted from both the free water and the suspended matter, whereas LSE mainly analyzes contaminants dissolved in the water.

As large amounts of mostly toxic and flammable solvents are required for extraction, LLE is not an environmentally friendly or economic method. The formation of emulsions during extraction, additional clean-up and solvent evaporation steps can cause some reproducibility problems or even the loss of analytes. These features make automation difficult. Hence, there is a general trend to substitute current LLE procedures by LSE protocols.

4.1.2 Liquid–Solid Extraction and Solid-phase Extraction

The SPE method corresponds to the current trend towards automation and establishing environmentally friendly techniques in laboratories.

It can be used off-line, or on-line linked up to a chromatographic device. The separate operation of the extraction step from analysis has some advantages regarding the versatility of application. In method development, for varying extraction problems (matrix, concentration), and for on-site sampling, an instrument-independent SPE step is favored. Furthermore, the eluates obtained can be extensively treated as often as required and analyzed using different methods. Automation is possible using preparation units that sequentially extract the samples and clean them up for automatic injections.

Nevertheless, there is a general trend towards on-line combinations because fully automatic systems allow high sample throughput without any loss in analytical performance. Generally, reproducibility and detection limits are improved because the closed system minimizes the loss of analytes and limits sample manipulation problems. Unfortunately, the restricted size of the precolumns may cause problems with low-breakthrough analytes such as phenol.\(^{(47)}\)

Off-line techniques have the disadvantage of lower sensitivities owing to the injection of an aliquot and analyte loss during the evaporation steps. On-line coupling of SPE to the chromatographic system avoids these problems. Moreover, the sample volume can be reduced because the entire sample is transferred and analyzed.

LSE combines all the techniques that use the analyte partition between a solid and a corresponding liquid phase in order to separate and accumulate the target compounds from an aqueous sample. The separation mechanisms are based on absorption as well as adsorption phenomena without achieving partition equilibria at any points of extraction. Several liquid chromatographic methods also belong to this category and may be conveniently combined with SPE as a prior sample enrichment and clean-up procedure.

Numerous sorbent materials are commercially available for various purposes. Suitable surface modifications adapted to special extraction problems may solve most of the sample enrichment problems in environmental analysis. The bonded silica used until recently is being increasingly substituted by polymeric sorbents with higher capacity and efficiency regarding the extraction of polar compounds, such as the phenols.\(^{(47)}\)

Prefabricated sorbent material packed as columns, cartridges and disks are supplied by various manufacturers. The larger the active sorbent surface, the more effective is the extraction of polar compounds. Consequently, highly porous supports and strongly cross-linked coatings have gained acceptance. Breakthrough volumes, recoveries and detection limits related to sample volume and the analyzer used are important parameters for characterizing SPE performance. Lichrolut EN\(^{47}\) (available from Merck), a very suitable sorbent for the extraction of polar compounds, allows the trace-level detection of the phenols listed in Table 2 from ground- and river water with recoveries of 80% and higher.\(^{(45)}\)

Several surface and coating modifications have been examined to increase the capacity of sorbents and to improve the analytes’ extraction and desorption behavior. Beneficial modifications have been achieved by acetylation, hydroxymethylation, or sulfonation,\(^{(48)}\) providing improved recoveries for several compounds such as phenol and catechol with low breakthrough volumes on commercially produced SPE material.

One material that predominantly adsorbs analytes is based on graphitized carbon. Other than for phenol itself, the extraction of phenolics from water is basically possible at a recovery of about 90%.,\(^{(49,50)}\) The inherent difficulties of analyte desorption are due to the excessive or even irreversible retardation of the adsorbed molecules, such as 2,4-dimethylphenol. Backflash elution may improve the desorption but is difficult to automate. Some improvements in mechanical stability and the handling of carbon-derived sorbents have been achieved by immobilizing porous graphite carbon on a silica surface. This modification showed good results for the concentration of aminophenols and of the highly polar catechol.\(^{(49)}\)

Heating or microwave excitation may also support the yield and the selectivity of the desorption step.\(^{(51)}\)

The development of new sorbent materials continues for improved selectivity (see also section 6.2), capacity, stability, and feasibility for field application.

Very different sorbent breakthrough volumes as exhibited by the phenols may cause problems in simultaneous determination. For example, high sorption capacities for PCP contrast with low adsorption capability for phenol, monochlorophenols, and nitrophenols. Although the new Empore\(^{tm}\) disk containing a polystyrene–divinylbenzene copolymer can compensate for insufficient recoveries of
the chlorophenols, phenol still remains a problem with just 20% recovery.

### 4.1.3 Derivatization

As described in section 2.5, derivatization is particularly required in phenols determination when using GC separation techniques. Due to the high polarity and low volatility of some phenols, a derivatization step improves thermal stability, gas chromatographic behavior of the analytes, and most notably the selectivity and sensitivity of detection. Commonly used derivatization reagents are listed in Table 3.\(^{52}\)

Typically, three basic reactions are recommended for the derivatization of the hydroxy group of phenols. O-Acylation, silylation and alkylation are possible, with the

selection of the most suitable reagent depending on the analysis method applied. Acylation converts compounds with active hydrogens, such as phenols or alcohols, into esters through the action of carboxylic acids, anhydrides, or carboxylic acid halogenides. Alkylation replaces the active hydrogen by an aliphatic or aliphatic-aromatic group and silylation forms trimethylsilyl ether. The GC retention times of the derivatives are influenced in various ways. Acylation decreases retention due to the increased volatility of the products. In contrast, trimethylsilylation mostly delays the retention times.

The highest detection sensitivity is obtained in combination with fluorine-containing reagents and GC/ECD analysis. As MS detection and even tandem mass spectrometry (MS/MS) techniques are available, a derivatization reagent should be chosen that produces characteristic fragment ions to improve identification. For example, the introduction of a trimethylsilyl (TMS) group results in quite abundant ions representing the complete derivative. Introduction of a trimethylsilyl group at 73 amu ((CH$_3$)$_3$Si$^+$) and methyl abstraction from the molecular ion (M–CH$_3$)$^+$. The molecular ions of the TMS derivatives often appear weak. More predominant in the mass spectrum are the molecular ions of the trifluoroacetyl (TFA) derivatives. Furthermore, every spectrum of such a phenol derivative is marked by the characteristic loss of the TFA group (M–CF$_3$CO$^+$). This fragmentation can be used by MS/MS techniques for the highly selective detection of phenolic compounds even without preseparation of the total mixture. The rapid screening of lignite-derived wastewaters and asphaltene products is also possible.

The lack of specificity of most reagents should be mentioned as a disadvantage of derivatization because reactions with other compounds bearing acidic hydrogens, such as amines, mercaptans, alcohols, and carboxylic acids, cannot be prevented without prior clean-up. Furthermore, undesirable by-products such as acids are formed during reactions with anhydrides and acylhalogenides. Such aggressive by-products such as acids are formed during reactions with anhydrides and acylhalogenides. Such aggressive by-products have to be removed prior to GC analysis, in order to avoid damaging the GC separation phase. In this respect perfluoroacylimidazol is preferred because no interfering by-products occur.

Similarly, in the HPLC/UV analysis of phenols, sensitivity can be improved by postcolumn photochemical derivatization reactions. The UV-initiated decomposition of dansyl derivatives of phenolic compounds in a methanol–water mixture leads to the formation of highly fluorescent dansyl hydroxides or dansyl methoxides. Detection limits below the nanogram per liter level can be achieved by dansyl derivatization and direct fluorescence detection. Fluorescence can also be used to detect phenols at trace levels without derivatization.

4.1.4 Liquid–Solid Extraction and Solid-phase Microextraction

Another emerging approach combines sample preparation and analysis. The SPME method is a solvent-free LSE technique when combined with GC. Combination with GC, HPLC, or capillary electrophoresis (CE) allows the analysis of different pollutant classes from the air, water and soil–water slurries at trace-level concentrations. A comprehensive review of the theoretical and practical aspects of SPME is given by Pawliszyn.

The SPME technique is not easy to classify as merely a sample preparation or a sample introduction method that transfers analyte molecules into an analytical system, because SPME combines both aspects. The main advantage is the absence of any solvent within the extraction step, which complies with the current trend towards the development of environmentally friendly and economic analytical methodologies. Furthermore, particularly high sensitivities may be achieved for substances with high octanol–water coefficients (log $K_{ow}$). First described by Pawliszyn and coworkers, SPME is a simple, rapid and inexpensive method which may be conveniently introduced into laboratory protocols. It is now commercially available as an automated technique coupled on-line to a gas chromatograph (Varian autosampler). A fused silica fiber coated with a polymer film is fixed inside a syringe (Figure 2).

For analysis, the fiber is exposed to the sample and the analytes are absorbed in the stationary phase until their partition equilibrium is reached. Additional sample filtration prior to extraction is not needed. After extraction, the fiber is then removed from the sample and the analytes trapped are thermally desorbed in the injector of a gas chromatograph. Care and attention has to be paid to septum leaks which can arise when the SPME needle penetrates the GC septum, but numerous reports have proved the high reproducibility and reliability of SPME/GC if professionally applied.

Different fiber coating materials with specific selectivity and extraction mechanisms (absorptive, adsorbive) and appropriate SPME fiber assemblies are commercially available. In principle, SPME coating materials are very similar to the polymers used in the stationary phase of GC. Of the diverse range of coatings examined for phenol determination, polyacrylate (PA) has proved to be the most suitable.

The SPME technique was first used to analyze phenols by Buchholz and Pawliszyn. The detection limits for the phenolics included in the USEPA 604 method were in the nanogram per liter range using GC/FID and GC/MS. The optimized protocol used a saturated sodium chloride solution at pH 2 to increase SPME sensitivity. The optimum sampling time depends on the sample matrix, namely on the diffusion coefficients of the
Figure 2  Syringe assembly for SPME and individual sampling steps. 1. The SPME fiber is exposed to headspace (a) or in liquid (b) while suitable agitation of the sample (stirring, sonication, fiber vibration) takes place. 2. After the extraction period, the fiber is rejected and removed from the sample. 3. Thermal (c) or solvent-assisted (d) desorption of the sample into the GC (c) or HPLC (d) instrument.

analyses under the respective conditions. As they can vary between 30 min and 1 h, optimization prior to a series of analyses is recommended.

For comparison, the GC/MS analysis of a phenol mixture was performed on samples prepared by directly injecting an extract and by SPME of the aqueous sample (Figure 3).

Although derivatization before and/or during SPME sampling can enhance the sensitivity and selectivity of analysis, the incorporation of this additional step typically complicates the entire process, and should only be considered when necessary. Quantification requires some additional effort to ensure reproducible results.

Higher amounts of organic matter can influence the extraction process, recoveries and detection limits achieved by delay of the analyte diffusion or by partial blocking of the surface coating. In these cases, reliable quantification requires standard addition to compensate for complex matrix effects. Standard addition involves the multiple, phased addition of defined amounts of suitable reference compounds and subsequent analysis. The resulting relationship between analytical values detected and the analyte amounts added gives a calibration curve whose regression leads to the initial concentration of the target analyte in the original sample. This additional step is only needed in the presence of interfering matrix material; otherwise, for low-matrix-polluted waters, such as tap water or groundwater, quantification using an internal, usually isotope-labeled, standard is recommended.

In contrast to SPE, the SPME techniques have significant advantages of time and lower solvent consumption per analysis (Figure 4). The SPME technique also has potential use with mobile and miniaturized GC devices for on-site measurements.

4.2 Preparation of Solid and Gaseous Samples

Typical procedures for sample preparation of solid material involve LSE with an organic solvent followed by both clean-up and concentration stages. This methodology is time-consuming and costly in the amount of toxic solvents required. Furthermore, aggressive shaking and/or temperature conditions are required to release the analytes adsorbed on the soil matrix. The conventionally used method to extract organic pollutants from soil is Soxhlet extraction, which consists of a simple distillation process repeated a number of times. In total, extraction times vary between 4 and 24 h depending on the soil material and the analytes to be extracted. Alternatively, the soil slurry can be sonicated but with the risk of a lack of sensitivity owing to possible analyte degradations.

Thermally and pressure-assisted extractions, generally described as enhanced solvent extraction (ESE), are increasingly being applied and accepted by official regulations. Examples are, supercritical fluid extraction...
(SFE) and accelerated solvent extraction (ASE\textsuperscript{m}). Microwave-assisted sample extraction has also been introduced into sample preparation protocols.

### 4.2.1 Subcritical and Supercritical Fluid Extraction

Since the rapid developments of supercritical fluid chromatography in the 1980s, SFE has been considered as a sample preparation technique in environmental analysis owing to its efficiency and time-saving extraction capabilities. Summaries and method reviews have been given by Hedrick et al.,\textsuperscript{68} Barnabas et al.\textsuperscript{69} and Bøwadt and Hawthorne.\textsuperscript{70}

In practice, more than 90\% of all analytical SFE applications use carbon dioxide (CO\textsubscript{2}) as the supercritical fluid due to its low critical pressure of 74 bar and critical temperature of 32 \( ^\circ\text{C} \). Carbon dioxide is also nontoxic, is not flammable or explosive, is chemically inert, and is easy to remove after extraction; however it is not sufficiently polar to extract phenols. At supercritical conditions carbon dioxide has a comparable polarity to liquid pentane, and is therefore an excellent fluid for the extraction of lipophilic compounds. A few percent of an organic solvent such as methanol are often added as modifier to enhance the solubility of more polar compounds. Alternatively, the polarity of the analytes can be reduced by derivatization or complexation using chelating agents in order to improve the SFE efficiency. For example, chlorinated phenols from sediments were derivatized in situ using acetic anhydride in the presence of triethylamine. The subsequent SFE was carried out with CO\textsubscript{2} at 80 \( ^\circ\text{C} \) and 370 bar using 10 min of static extraction and 5 min of dynamic extraction with a flow rate of 2 mL min\textsuperscript{-1}. The recoveries obtained varied between 84\% and 100\%\textsuperscript{71}. Apart from several advantages for the extraction of lipophilic compounds from solid matter, SFE has not won wide recognition in phenol determination because it is not easy to use for routine analyses. Moreover, commercial apparatus is expensive and not very widespread.

Extraction methods using organic solvents or even water at moderate pressure and temperature have been used. Under specific conditions, water is an ideal solvent for a wide range of pollutants of different polarity. The intrinsic polarity of water supports the preferred extraction of polar phenols. By changing the temperature at moderate pressure (subcritical conditions), a wide range of water polarities can be achieved\textsuperscript{72} which allows the sequential extraction of different polar compounds from soil; however, supercritical water may be corrosive to stainless steel vessels, thus the operator should take care\textsuperscript{72}.

For GC analysis the analytes have to be transferred from water into an organic solvent (e.g. trichloromethane). After release of the water extract from the extraction cell, it bubbles through an organic solvent and the analytes partition between both phases. This step may lower the extraction efficiency of polar compounds owing to their high water solubility. Additional

---

**Figure 3** Lower trace shows the GC/MS chromatogram of the USEPA 604 phenols directly injected from a mixture of defined concentration. The upper trace is of the same mixture sampled and analyzed by SPME using a PA fiber coating.
LLE steps, also assisted by sonication, SPE or SPME, can enhance the recoveries. Chlorinated phenols can be efficiently extracted by subcritical water, as the recoveries of 96–100% prove.

4.2.2 Accelerated Solvent Extraction

The ASE™ protocols, used for the extraction of basic, neutral and acidic environmentally relevant compounds from solid samples, meet the requirements of official methods such as USEPA 3545. Commonly used solvents are applied to the extraction from solid material under increased pressure (10 MPa) and temperature (100°C) conditions. The extraction conditions change the properties of the solvents and improve the wetting of solid surfaces. The release of analytes from the solid matrix is possible in shorter times (usually 12 min) and is managed with a small volume of solvent, about 15 mL per 10 g of soil. The fully automated process is easy to operate and gives recoveries that are comparable with Soxhlet extraction.

For example, the extraction of nonylphenols from soil and solid material can be performed by Soxhlet extraction, steam distillation/solvent extraction or more economically by ASE™ and SFE. Optimal yields of nonylphenols were obtained by ASE™ using pure methanol and a fairly low pressure of about 15 MPa.

Following hot water extraction or an aqueous ASE™ of the contaminated solid materials, the incidental water extracts are analyzed by SPME/GC/MS.

Optimum ASE™ conditions using water as solvent for the extraction of soil spiked with USEPA 604 phenols are 10 MPa at 125°C. The extraction cycle of 10 min is repeated three times. The addition of 5% (v/v) acetonitrile as solvent modifier can improve phenol recovery slightly. The detection limits obtained after SPME/GCMS analysis range from 1.1 µg kg⁻¹ for 2-chlorophenol to 6.7 µg kg⁻¹ for 4-chloro-3-methylphenol. The SPME sampling was performed with a PA fiber coating at conditions currently used for SPME of phenols. The ASE™ methodology using only pure water gave slightly higher detection limits, but within the lower microgram per kilogram range.

Optimum conditions obtained for the extraction of spiked soils are usually less efficient when real samples are extracted. Thus extraction efficiencies are overestimated, especially in cases of strongly different soil matrices (such as by varying the content of organic matter).

4.2.3 Microwave-assisted Extraction

The number of procedures using microwave-assisted extraction (MAE) of organic compounds from environmental samples is increasing. Agitation by microwave energy causes molecular motion by migration of ions and rotation of dipoles without changing of molecular structures. The theory and main applications of microwave-assisted processes (MAP™) are well described by Dupeyron et al. and Paré et al.

Only dipole-containing compounds are affected by microwaves. Therefore, with nonpolar solvents such as hexane or toluene, polar additives such as acetone are required. The main advantages of microwave use are the reduction of solvent, shorter extraction times, and the greater number of samples that can be simultaneously extracted. In an experimental set-up MAE and the most currently used Soxhlet extraction were compared using a phenol-spiked clay soil from an industrial downfall. The recoveries for most of the phenols studied were comparable. 2-Methylphenol and 2-nitrophenol gave better results with MAE. Generally, low recoveries for alkylated phenols are reported, probably attributable to intensive analyte–soil interactions.
In every case, the extracts contain, among the phenols, a great variety of matrix compounds and a clean-up using LC on alumina, silica gel or aluminosilicates is required.\textsuperscript{86,87} Gel permeation chromatography or preparative HPLC can improve and automate this cleaning process.

As the organic solvents have been replaced by water, the resulting aqueous extracts can be immediately sampled and analyzed by SPME/GC/MS.

### 4.2.4 Air Monitoring

Compared to soil and wastewater, air samples are easier to handle. The decisive and most important step is the enrichment of phenols under defined conditions. Passive and active (or dynamic) sampling are the two main ways for collecting phenols from gaseous samples. Canisters, sampling bags and bulbs commonly used in air sampling are not suited for polar and surface-active analytes (like phenols). Despite passivation of the canister and bag materials a nonreversible adsorption of phenol cannot be prevented completely. Sorbent tubes provide a low-cost and versatile alternative to containers.\textsuperscript{88} The active air sampling onto sorbent tubes needs only a convenient pump assembly and a thermodesorption interface for subsequent GC analysis. Tubes prepacked with sorbents are commercially available, such as Tenax\textsuperscript{TM}, Chromosorb\textsuperscript{TM}, Carbopack\textsuperscript{TM}, or Amberlite XAD\textsuperscript{TM} resins. They can be used individually or in combinations of two or three.\textsuperscript{35} After desorption they are ready for reuse, but after a longer storage period the sorbents should be cleaned thermally. The sorbents used are stable enough for about 100 cycles before they have to be replaced. The most sensitive parameter that has to be considered in method development is the breakthrough volume of the analytes of interest, which depends on the amount and quality of sorbents used in the tube. Also important is the gas flow used for conditioning, sampling and desorption, the influence of humidity during sampling, and operating temperatures, especially those of the desorption step. The desorbed analytes are collected on a cooled focusing trap prior to GC analysis. After desorption the trap is heated to transfer the analytes to the GC capillary for analysis. The USEPA air monitoring methods (TO-8 and TO-17) can be used to select the appropriate procedures for the determination of volatile phenols in gaseous samples.

### 5 Instrumental Techniques

#### 5.1 Gas Chromatography

The analytical approaches most frequently used in conjunction with LLE and LSE are GC and LC. In particular, GC is combined with FID, ECD, or MS. Each combination is accepted by official USEPA methods. Of the detectors, MS is the most sensitive and selective, including the identification of unknown components. However, FID and especially ECD (which is highly selective and sensitive for polyhalogenated compounds) are more affordable and are therefore widely used in the routine determination of priority phenolics.

For the determination of endocrine-disrupting phenols (e.g., nonylphenols) and their precursors, the alcohol ethoxylates, a number of method combinations are available.\textsuperscript{89} Off-line SPE is the preferred enrichment procedure from water samples using Amberlite XAD\textsuperscript{TM}-2 and XAD\textsuperscript{TM}-4. Excellent recoveries of 90–100% have been obtained using four different solvents for SPE elution.\textsuperscript{90} GC/MS and HPLC/UV are the most favored analytical methods for determination. The most easy, solvent- and time-saving procedure with which to determine nonylphenols in aqueous samples is SPME/GC/MS using a PA or poly(dimethylsiloxane)/divinylbenzene (PDMS/DVB)-coated fiber. Detection limits for the nonylphenol isomers are between 1 and 10 µg L\textsuperscript{-1}.

#### 5.2 High-performance Liquid Chromatography

The most commonly used procedure for the extraction and concentration of phenolics from aqueous samples is LSE, and on-line coupling to HPLC is becoming increasingly popular. This configuration does not require any prederivatization steps, especially for phenol determination.

Octadecyl (C\textsubscript{18}) and octyl (C\textsubscript{8}) HPLC columns are currently used to determine phenols. Although most phenols may be detected by UV at 280 nm, the detection of nitrophenols and PCP is usually more sensitive at 310 nm.\textsuperscript{35,91} Full spectral information is obtainable using a diode array detector, which may assist in the identification of unknowns or the confirmation of assigned analytes by spectra libraries usually contained in the software packages of HPLC instruments. Table 2 compares the on-line and off-line SPE/HPLC/UV analysis of selected phenols, showing the clear advantages of on-line coupling.\textsuperscript{45} Otherwise, the detection limits depend strongly on the detector used. Electrochemical detection instead of UV can improve sensitivity by a factor between 10 and 100.\textsuperscript{92,93}

The high detection sensitivity results in a possible reduction of sample volume which complies well with on-line SPE/LC and minimizes the input of interfering material. Unfortunately, oxidation-susceptible matrix components can interfere with the background current, resulting in low reproducibility of the detection.

If a high oxidizing material content is present then cleaning of the detector cell is frequently required...
to restore the initial response, so that electrochemical detectors are not necessarily advisable for automated wastewater analysis. The use of biosensors as LC detectors can overcome some of these problems because of their high analyte specificity, but unfortunately there is still a lack of sensitivity.

Coulometric detection has not found widespread acceptance in spite of the low detection limits attainable. The increase in sensitivity as compared to the usual electrochemical detector is caused by nearly complete oxidation of the analyte inside a porous electrode. The more sophisticated and therefore more expensive variant is an array detector, which further improves the detection limits (0.03 and 0.38 ng L\(^{-1}\)) and extends the analyte response.

Special equipment is required to couple MS with LC. Today several LC/MS interfaces are available. Nearly all the currently used interfaces have been examined for phenol determination but only a few give full responses for the entire list of priority phenols. For example, thermospray is not suited to the ionization of phenol and some methylated phenols.\(^{94}\) The technique is based on ion formation by the addition of volatile buffers and thermally assisted release of the solvent. Under these conditions most phenols produce negative ions by deprotonation, excepting the few acidic phenols.

Particle beam interface is not successful in phenol analysis because of its low sensitivity.\(^{95}\)

The LC/MS interfaces, generally classified as atmospheric pressure ionization (API) interfaces, are the most promising in phenols analysis. The interface with the highest sensitivity for phenols is atmospheric pressure chemical ionization (APCI).\(^ {96,97}\) Ion formation occurs by acid/base reactions already in the liquid phase of the LC eluent and additionally in the gas phase of the spray produced by a corona discharge electrode. A suitable buffer ensures hydrogen abstraction from the phenolic hydroxyl group, and produces negative pseudo-molecular ions (M–H\(^{-}\)). The coupling of APCI/MS with on-line SPE using Lichrolut EN\(^ {30}\) as sorbent in selected ion monitoring (SIM) mode gives detection limits in the nanogram per liter range. Even in full-scan operation the detection limit ranges from 0.5 µg L\(^{-1}\) for 4-nitrophenol to 20 µg L\(^{-1}\) for 2,4-dimethylphenol.\(^ {97}\)

The same trend as for thermospray ionization is observed, in that phenol, methyl-, dimethyl- and also the monochlorophenols show lower sensitivities than the more acidic phenols, such as the nitro-substituted analogs. However, electrospray or ion spray interfaces can be used that provide more ion abundance, particularly for the phenols that are problematic to APCI. In this approach the post-column addition of volatile basic buffers such as triethylamine or KOH solution is required to generate phenolate ions.\(^ {98}\) In API method development, very careful optimization of both separation and ionization techniques is necessary to obtain maximum sensitivity at optimum reproducibility. For example, phenols require acidic conditions for LC separation but a basic pH for API ionization. In addition to these additional operational difficulties matrix components such as humic matter can negatively interfere with the method response and system stability. The newest development of an orthogonally configured spray needle can delay contamination and blocking of the sample cone and skimmer assembly by solid matter. An important advantage of MS detection is its eminent suitability for the screening of unknowns, especially when the mass spectrometric information can be improved by collision-induced dissociation (CID). For this purpose an additional potential is set to either the cone voltage or to an octapole field (instrument specific). Both variants result in an increase in fragmentation of the normally predominating pseudomolecular ion. Unfortunately, interpretation of the resulting more ion-rich spectrum needs considerable experience and cannot be confirmed by commercially available spectra libraries. This is a general problem in API applications because the majority of differences are instrument dependent. Finally, more expensive instruments with MS/MS functionality can be used for structure elucidation.

Ongoing developments in HPLC (e.g. new micro-columns and capillary columns), in MS (e.g. the coupling of API with MS/MS capable ion traps), or fast-scanning time-of-flight instruments will further increase the attraction of LC/API/MS in environmental trace analysis.

5.3 Capillary Zone Electrophoresis

In addition to phenol determination by ion chromatography,\(^ {99}\) electrophoretic separation is of interest in the analysis of ionic and polar molecules, including the phenols. The main advantages are high chromatographic resolution, and sample enrichment in the capillary by isotachophoresis\(^ {100}\) which may compensate the low loading capacity of CE. Furthermore, the normally disturbing matrix components such as humic and fulvic acids are separated from the analytes by their strongly different migration behavior.

The most common electrolytes are sodium borate or phosphate buffer,\(^ {101}\) which have to be replaced by volatile buffer systems if electrospray ionization (ESI)/MS detection is used; however, UV detection is generally favored. The combination of off-line SPE and capillary zone electrophoresis (CZE)/UV gives detection limits of phenols at low microgram per liter levels.\(^ {101}\) As a result of the basic electrolyte conditions and the high voltage applied, undesirable reactions such as hydrolysis or polymerization of phenols can occur. This can be overcome by micellar electrokinetic chromatography using sodium dodecyl sulfate (SDS) as an additive.\(^ {100}\)
6 NEW DEVELOPMENTS

6.1 Sensors

Most biosensors have been developed based on phenol-oxidizing enzymes coupled to an amperometric detection system. A typical example is shown in Figure 5. Tyrosinase (EC 1.14.18.1), laccase (EC 1.10.3.2) and various peroxidases (horseradish peroxidase) are used as receptor compounds. For example, the tetrameric enzyme tyrosinase which contains 1 mol active copper(I) per monomer catalyses the ortho hydroxylation of phenol to catechol and additionally the dehydrogenation of catechol to orthoquinone. The oxidation of para-substituted phenols is usually catalyzed. The oxygen consumption of an enzymatic cycles can then be used as sensor for phenols oxidized within the process. Alternatively, the electroactive quinoid products can be detected at a cathodically potentiostated carbon electrode. An amplification of the enzymatic electrochemical signal is obtained when the orthoquinone is again reduced via catalytically active conducting polymer or redox mediators. Ferrocyanide, tetracyanochinodimethane, or 5-methylphenazonium cations usually act as electron shuttles between the cathode and the orthoquinoid products of the enzyme reaction.

Sensor developments are focused on improvements in sensitivity, enhanced resistance against changing medium conditions (pH, temperature), the influence of inorganic and organic matrix components, improved long-term stability, and robustness for field application.

Sensor stability depends strongly on the kind of enzyme immobilization on the transducer surface. Different possibilities have been examined to fix the enzyme, such as behind a dialysis membrane, mixing in graphite powder and hexadecanol, carbon paste, epoxy/graphite, in a composite of carbon paste/polyamide or tyrosinase immobilized by entrapment within a polycarbamoylsulfonate polymer. The latter variant is marked by high sensitivity for 2,4-dimethylphenol (635% related to phenol as 100%), 4-chlorophenol (225%), and 4-methylphenol (185%). In total this special biosensor responds to eight phenols, including phenol, catechol, 2,4-dimethylphenol, and para-substituted phenols. The detection of meta- and ortho-substituted phenols is not possible due to the specificity of the catalytic process, which forms intermediate quinoid structures. The optimum pH of sensor operation is 7.0, within a narrow pH range of 6.5–7.2 where 90% of the maximum response is retained. The influence of temperature is restricted to the range 10–30°C; below and above this range the enzyme activity decreases and a loss of steady-state stability occurs, respectively.

Long-term stability of 100 days is guaranteed when the sensor is stored at 5°C in buffer solution or dry at −18°C. Very short analysis times of 6 min including rinsing of the sensor and adjustment to the initial baseline, detection limits in the low microgram per liter range, and cost-effective production of biosensors – especially on the basis of screen-printing technology using polymer pastes – make this method attractive for field applications.

Tyrosinase is often implemented in phenol biosensors and co-immobilized with laccase. The range of detectable phenols is extended by additional responses from hydroquinone and 2-amino-4-chlorophenol. For the analysis of vapors containing phenols an enzyme/gas-diffusion electrode with tyrosinase has been investigated that allowed the determination of phenol in the ppm range.

Biosensors using cells of Pseudomonas putida have been designed for the determination of phenol, benzoic acid and their monochlorinated derivatives from water and hexane solutions. This approach is based on oxygen consumption in relation to the analyte oxidation and, therefore, on the cells immobilized on an oxygen electrode. The detection limit obtained for phenol was 0.1 µM and for chlorophenols 8 µM. Different cell induction procedures influenced the sensor selectivity, thus the selective production of various sensor types should be possible in the future. The intrinsic specificity and rapid operation of biosensors make them potentially interesting for fast screening in field analysis and, in combination with SPE, for selective detection coupled to LC.
A review covering the development of sensor arrays and their applications is given by Carey.\textsuperscript{117}

6.2 Immunoassay

The immunoassay methods combine a rapid and inexpensive analysis with high analyte specificity at low expenditure in sample preparation.\textsuperscript{118} They are promising for on-site measurements to select samples for more detailed analysis and for early-warning purposes. In the USA, the immunoassay approach has been implemented in many environmental pollution studies, together with the use of conventional techniques such as confirmation by GC/MS.\textsuperscript{94}

Although considerable effort has been devoted to the development of immunoassays only a few are available, such as for PCP. The assay features high selectivity and low response to matrix influences.\textsuperscript{119} Only for two tetrachlorophenols (2,4,5,6- and 2,3,4,6-) was significant cross-reactivity observed (54.1\% and 15.1\%, respectively), and a detection limit for PCP of 60 ng L\(^{-1}\) emphasizes suitability as a specific trace method.

In comparative studies the immunoassay values were confirmed by accepted methods (GC/MS and HPLC). Further developments tend to assay applications for toxins including phenols in biological materials. 4-Nitro- and 2,4-dinitrophenol in urine and water samples could be detected with limits of 7 µg L\(^{-1}\).\textsuperscript{120} As this immunoassay is for LC detection, an 8–10-fold higher sensitivity is achieved than with UV detection. The adjustment of an immunoassay for HPLC detection is difficult to achieve because of the incompatibility of antibodies and organic solvents used for HPLC separation.

Immunoassays are best suited for the detection of selected phenols after ASE\textsuperscript{™} with water or SFE if a water-based collection solvent is used. Progress in biotechnological research and molecular design is likely to extend the development of immunoassays to a wider range of applications.

PHENOLS ANALYSIS IN ENVIRONMENTAL SAMPLES

Polychlorinated Biphenyls Analysis in Environmental Samples

Bert van Bavel, Mats Tysklind, and Gunilla Lindström
Umeå University, Umeå, Sweden

1 INTRODUCTION

Production of PCBs, which are characterized by containing several of the 209 possible chlorination products of biphenyl, occurred mainly from 1930 to the late 1970s. An overall world production until 1980 of $2 \times 10^9$ kg has been estimated.\(^1\) As early as 1936 workplace threshold limits were set due to toxic effects observed in connection with occupational exposure. But the widespread environmental contamination and its effects were not fully accounted for until the late 1960s, when the global occurrence of PCBs in all biological material was shown to be a fact. In the 1960s chemists using the newly introduced GC techniques to analyze chlorinated pesticides present in the lipid fraction of biological materials found interfering peaks in the chromatograms which soon were identified as being caused by bio-magnifying PCB residues.\(^2,3\) These findings eventually led to restrictions in the 1970s, in both the use and production of PCBs in most countries. Measures were also taken to minimize the generation and distribution of PCBs from secondary sources. Today, some thirty years and tens of thousands of PCB analyses later, our analytical techniques are tuned to detect each and every individual PCB congener down to parts per trillion (ppt) levels. And due to extensive efforts in combating the PCB problem since the 1980s, declining PCB trends are reported.

2 A SHORT HISTORY OF POLYCHLORINATED BIPHENYL ANALYSES IN ENVIRONMENTAL SAMPLES

The Swedish researcher Sören Jensen\(^2,4,5\) discovered PCBs in the environment using a packed column gas chromatograph with an electron capture detector. Traditionally, therefore, GC with ECD is used to analyze PCBs. Packed columns were originally used until capillary columns were introduced at the start of the 1980s. Major environmental monitoring studies were done using packed-column gas chromatography/electron capture detection (GC/ECD). Quantification was achieved by comparison with Aroclor\textsuperscript{TM} mixtures.\(^6\) Total areas analysis or quantification of individual congeners.\(^7\) While
changing from packed-column GC/ECD to capillary high-resolution gas chromatography (HRGC), problems involving quantification arise. Results acquired by the different methods are not directly comparable because of several basic differences. The main problem with using packed columns is the poor resolution of the PCBs. PCBs are represented as a poorly resolved series of peaks and reported as a total area or related to a commercial PCB mixture. The introduction of capillary gas columns improved the resolution and made it possible to produce congener-specific data. The next problem was that it was difficult to compare the old packed-column data with the newer high-resolution column data. The older methods used Aroclor™ mixtures as the external standards, based on specific peaks or total area. Although these methods can be applied with capillary gas chromatographic data, the errors in the determination become larger and more obvious due to differences in PCB pattern between the different samples. Thus it is difficult to compare levels of PCBs measured and quantified with different methods. Although largely dependent on the sample matrix, PCBs measured as the total area overestimate the “real” levels due to interferences (chlorinated pesticides or other halogenated compounds). The methods based on specific peak quantification generally result in higher levels for the packed column analysis although in some cases good agreement is observed. While capillary or HRGC columns offer a more specific and in most cases a more sensitive analysis, ECD was often used as the detection method. This technique specifically detects halogenated compounds and although interferences of nonhalogenated compounds are eliminated, it is still possible that halogenated compounds eluting at the same time are interfering. A large number of chlorinated pesticides and brominated flame retardants are known to elute within the same time window as PCBs. Often the HRGC resolution will be enough to separate these compounds from the PCBs, but depending on the levels the interferences might cause erratic, higher, values for some of the PCB congeners. The quest for more specificity and in some cases more sensitivity has resulted in the use of MS as the detection technique instead of ECD. The specificity is enhanced by monitoring the molecular ions of the PCBs in combination with their unique molecular chlorine clusters. Gas chromatography/mass spectrometry (GC/MS) in combination with the use of 13C-labeled internal standards has become the preferred detection method using ion-trap or quadrupole MS. High-resolution mass spectrometry (HRMS) using magnetic sector instruments is nowadays often used for specific applications (planar PCBs) to further enhance specificity and detection levels.

### 3 STATE-OF-THE-ART ANALYTICAL METHODOLOGIES

With respect to the analysis of PCBs it is important to note that there are 209 different PCB compounds, with different properties and environmental behaviors. The basic chemical structure is given in Figure 1 and chlorine substitution at the different positions is indicated by a number on the first ring (1–5) and/or the second ring (1′–5′) as illustrated. To facilitate the reporting of the different PCB congeners, Ballschmiter and Zell organized the 209 PCBs into numerical order and assigned IUPAC numbers from 1 to 209. Throughout this article these so-called Ballschmiter numbers are used for identification of the different PCBs. One example of the different properties of the 209 PCBs is the lower bioaccumulation potential of the less chlorinated PCBs as compared with the more chlorinated PCBs. More subtle substitution differences, like chlorine substitution in the meta or para position, will also influence bioaccumulation. Even more important with respect to the analysis of PCBs in environmental samples are the differences in toxicity of the different congeners. PCBs that can adopt a planar or coplanar configuration show dioxin-like toxicity and are known to inhibit 7-ethoxyresorufin-O-deethylase (EROD) activity. It might therefore be important to specifically analyze these isomers as well as the most abundant PCBs or total PCB levels. A listing of the dioxin-like PCBs according to the World Health Organization (WHO) is given in Table 1. This table shows that PCBs with no or only one chlorine in the ortho position are assigned a so-called TEF value in relation to the toxicity of 2,3,7,8-tetrachlorodibenzo-p-dioxin. Toxicological considerations are not the only reason for congener-specific PCB analysis; the large differences in PCB patterns in environmental samples are another reason. Because of these large differences in the PCB patterns it is not very useful to report a sum parameter, the sum of only seven isomers, or to relate the levels to a commercial PCB oil mixture (such as Aroclor™). The differences in PCB patterns are illustrated in Figure 2, where the PCB patterns of both human and whale samples are shown. The whale sample contains nearly

![Figure 1](attachment:chemical_structure.png)
every PCB present in commercial PCB oils. In the human sample several PCBs present in a commercial mixture are metabolized. Although within species and within samples from the same origin sum parameters might be useful, this is certainly not the case when different sample types are to be compared. The emphasis is thus on congener-specific PCB analysis.

Nowadays most analytical methods use capillary GC columns to achieve gas chromatographic separation of the PCBs. Generally a nonpolar DB-5™ column (5% diphenyl dimethyl siloxane) is used for analysis with different column diameters (0.15–0.50 mm), film thicknesses (0.1–0.5 µm) and lengths (10–60 m). Different columns have been used and the retention order and relative retention times of the 209 PCBs on a variety of columns are now known. In some cases it is necessary to use another column to resolve co-elution or interference. One should be aware that the common use of the DB-5™ column in analysis has resulted in a generalization of the results. For example PCB #138 is reported in numerous reports, but it has been shown that this isomer co-elutes with PCB #163 (10–30% in environmental samples). In many reports PCB #138 is measured on a DB-5™-like column and thus actually reports the sum of PCB #138 and PCB #163. Several other co-elutions occur, and in some cases it is thus necessary to use two different GC columns.

ECD or MS is generally used for detection after GC separation. Depending on the type of samples and the questions to be answered the analytical method can be adapted. Although sample clean-up and extraction are important, the most important factor in choosing the analytical method is the detection. For many purposes ECD will be sufficient, but more and more MS detection is being favored. ECD is specific to halogen-containing molecules, and thus shows good sensitivity for the analysis of PCBs. It is also easily coupled to capillary columns and is fast enough to measure the PCBs eluting from the GC column even when fast GC and short columns are used. The disadvantage is that an ECD detector is unable to separate halogen compounds eluting at the same time as the target compound. For most applications ECD might still be good enough with the use of internal or external standard methods. Note that if an internal standard is added before sample extraction and clean-up using ECD, it must be a compound containing a halogen that is not present in the sample, and in some way resembles the analytical behavior of PCBs. With regard to the type of samples such a compound might be hard to find and often compromises have to be made.

Recently MS has gained in popularity due to the development of easy-to-use, benchtop instruments, most prominently low-resolution quadrupole and ion-trap instruments. With a low-resolution mass spectrometer it is possible to monitor specific masses, in most cases the molecular ion, to detect the target compounds. One specific property of chlorine, the existence of the natural isotopes 35Cl and 37Cl in a ratio of 3:1, can be used to identify or confirm the presence of any compound containing chlorine. An example of the typical chlorine cluster is given in Figure 3. A compound containing chlorine atoms shows a typical mass cluster and for PCBs this results in very specific mass spectra with peaks at the molecular mass (m) and two mass units higher (m + 2). Theoretically the ratio (m)/(m + 2) can be calculated and thus used to identify PCBs or as an extra QA/QC criterion. Another advantage of the use of MS is that 13C-labeled internal standards can be utilized during the sample extraction and clean-up. A 13C-labeled PCB is a synthesized stable isotope of the PCB, which exhibits the same chemical behavior as the “native” PCB. This implies that the 13C-labeled internal standards behave chemically in exactly the same way as the “native” PCBs. The only difference is in the mass, which is 12 units higher. The mass spectrometer can detect this difference in mass. This technique, which is called isotope dilution, allows the analytical chemist to use miscellaneous extraction

Figure 2 PCBs in (a) a whale and (b) a human sample. The most abundant congeners are indicated by their IUPAC number. This example clearly illustrates the differences in PCB patterns between the two samples. The whale sample contains nearly all of the congeners present in commercial PCB mixtures whereas the human sample only contains a number of specific congeners. Comparing noncongener-specific analyses of these samples is rather useless.

and clean-up techniques for qualitative analysis. These advantages over ECD as the detection technique make GC/MS the most prominent technique from a QA/QC point of view. In specific cases HRMS is used as the detection method. HRMS enhances the specificity by being more mass-specific, operating at a mass resolution of over 10 000 compared with a resolution of 100–1000 for a low-resolution instrument. Use of HRMS reduces the change due to interference at the more exact PCB masses monitored. More important though is the improvement in signal-to-noise ratio for high-resolution instruments, resulting in lower detection limits. HRMS is mostly used for the detection of the three planar PCBs (PCB #77, #126, #169). These PCBs are normally present in samples at 10–100 times lower concentrations than the normal “bulk” PCBs but are of toxicological importance as is evident from Table 1.

In conclusion it can be stated that there is no real universal method of analyzing PCBs. The preferred method depends on many factors, including sample type, levels and most of all the objective of the study. Questions on the accuracy of the results, expected levels, or objective of the study are preferably discussed before analysis. By doing this the analytical chemist can choose the best available technique for the purpose of the study. Because the extraction and clean-up techniques largely depend on the analytical detection technique that will be used in the end, the detection methods will be discussed in detail first, followed by the sample enrichment, clean-up and extraction techniques in later sections. For the interested reader many reviews and publications on the analytical chemistry of PCBs can be found in the international literature, but by far the most comprehensive publication is Analytical Chemistry of Polychlorinated Biphenyls by Erickson.(20) In addition, several standardized analytical procedures are described in more detail in this book.(20) Common United States Environmental Protection Agency (USEPA) procedures for PCB analyses include Methods 505, 508, 525, 608, 625, 680, 1618, 8080, 8081, 8250, 8270 and 8275.
3.1 Detection Methods

3.1.1 Gas Chromatography with Electron Capture Detection

GC/ECD is probably still the most used analytical technique for environmental samples because of its selectivity and high sensitivity for PCBs. Originally developed by Lovelock and Lipsky in the 1960s, ECD quickly became the most important analytical tool for the analysis of chlorinated environmental pollutants. The electron capture detector consists of a radioactive $\beta^-$ particle emitter ($^{63}$Ni), emitting towards an anode over an applied voltage (10–50 V), thus resulting in a current. When specific molecules with electron-adsorbing groups (halogens, nitrogroups or conjugated double bonds) pass by, these electrons are absorbed causing the current to drop, and this drop in current is recorded as the detector response. Modern electron capture detectors use pulsing signals to enhance the linear range. The linear range is around $10^4$ and ECD devices are able to detect 0.1 pg Cl $\text{s}^{-1}$. In Table 2, GC/ECD detection is compared with several other detection techniques used for the detection of PCBs. Although NCIMS in some cases produces a slightly better detection limit, the detection limit of GC/ECD is nearly as good. Compared with GC/NCIMS, ECD is much more stable and exhibits a larger linear range. GC/NCIMS is not normally used in routine analysis, which might be because of the difficulties in achieving stable ion source conditions during analysis while a reactant gas ion is flowing into the ion source. GC/ECD devices are nearly as sensitive as the much larger and thus more expensive HRMS instruments. These instruments however are much more selective because they use MS instead of the electron-absorbing capability of halogens. However from an instrumental point of view GC/ECD is easy to use and readily available in many configurations.

Until the development of capillary GC columns at the beginning of the 1980s, packed columns were used to separate the PCBs from each other and from other electron-absorbing compounds. In most cases these were other chlorinated environmental pollutants displaying the same properties as the PCBs, including the well-known pesticide dichlorodiphenyltrichloroethane (DDT) and its metabolites chlordane, hexachlorobenzene, aldrin and dieldrin. In some early publications using packed GC columns these compounds almost certainly interfered and resulted in an over-estimation of the real levels. Nowadays with the use of capillary columns the separation capacity has improved enormously but fractionation prior to analysis is often still necessary. It is therefore important to know which analytical detection method will be used before designing a sample clean-up procedure. Use of a less specific detection technique will require a more
rigorous sample clean-up and fractionation. It might also be necessary to run different fractions obtained during sample enrichment and clean-up separately, which might be avoided using a different detection technique (e.g. GC/MS). On the other hand the objective of the project is important; from a toxicological point of view the analysis of the three planar PCBs might need extensive fractionation while using GC/ECD, while if analyzing a PCB spill the sum of several PCBs might be sufficient and only minimal clean-up and fractionation is required.

### 3.1.2 Gas Chromatography Coupled to Mass Spectrometry

The preferred detection technique from an analytical point of view is GC/MS. Using GC/MS several additional QA/QC features can be added to the analytical method. Several MS instruments are available and benchtop instruments such as the ion trap or quadrupole are nowadays widely used in PCB analysis and are expected to replace GC/ECD more and more. In special cases high-resolution mass spectrometers are used, especially when the three planar PCBs (#77, #126 and #169) are to be analyzed at low levels or in the same fraction as toxicologically similar dioxins.

The mass spectrometer can be used in two ways:

1. to monitor all the masses in a certain mass range (full scan)
2. to monitor only specific masses in so-called selective ion monitoring (SIM) or selective ion recording (SIR).

Ionization can take place by means of electron impact (EI) or negative chemical ionization (NCI), a process similar to electron capture in the ECD device. Although NCI is somewhat more sensitive, as shown in Table 2, EI is by far the preferred method. This is probably because it is difficult to establish stable conditions in the ion source while the reactant gas is pumped into this source using NCI. Another reason might be that the relative response factors (RRFs) of the PCB homologs, that is PCBs with the same chlorination level, are not constant. This implies that more internal and quantification standards are needed. Accurate results have however been reported using GC/NCIMS.\(^{(122)}\)

The bombardment of the PCB molecules in the ion source during EI ionization results in very specific fragmentation of the PCBs. EI ionization is generally performed at 70 eV. Typical full-scan mass spectra are acquired over a mass range of 100–600 mass units at a scan speed of 1 scan s\(^{-1}\). Full-scan mass spectra from penta-, hexa-, hepta- and octachlorinated biphenyls are given in Figures 4–7. These mass spectra serve as a kind of fingerprint for the PCBs and in this way PCBs can be identified in environmental samples. Looking more closely at the mass spectra, a number of features can be used for quantitative analysis. First, from the molecular ion the two most abundant masses can be used to monitor the PCBs. One mass can be used to quantify the PCBs, and the other to confirm that it really is an undisturbed PCB.

a mass fragment at the same mass as the tetra-PCBs. Normally this is not a problem because these PCBs will be separated on the GC column.

One of the biggest advantages of GC/MS is that chemically identical $^{13}$C-labeled stable isotopes can be used as internal and recovery standards. This is illustrated in Figure 8, where a SIR GC/MS run of a human sample is shown. The top channel represents the mass (371.88) for the $^{13}$C-labeled internal standards added to the sample before sample extraction and clean-up and the recovery standard added just before GC injection. The lower two channels (359.84 and 361.64) are the two most abundant molecular ions of the PCBs actually present in the sample. The most abundant mass (359.84) is used for quantification; the other mass is used to compare its ratio with the theoretical ratio of $m_{C_2}$ and $m_{C_4}$ for a hexa-PCB (0.82). The three internal standards are used for quantification against an external standard containing at least one PCB at each chlorination level. The recovery standard is used to calculate the percentage of the internal standard lost during sample extraction, fractionation and clean-up.

The example above illustrates the capability of a low-resolution GC/MS system, in particular a quadrupole instrument. An ion-trap instrument performs in a similar way but can also be used for tandem mass spectrometry (MS/MS), to monitor specific fragments. Both instruments perform at mass resolution, which means that mass 360 can be separated from mass 361. High-resolution magnetic sector mass spectrometers operating at mass resolutions of 10,000 or more can differentiate between 359.96 and 360.00. This reduces the risk of interferences and significantly improves the signal-to-noise ratio. HRMS devices are thus somewhat more sensitive than the low-resolution instruments. For routine analysis of environmental samples it is not necessary to use HRMS. For several special applications, for example the analysis of the three planar PCBs (#77, #126, #169), high-resolution gas chromatography/high-resolution mass spectrometry (HRGC/HRMS) is widely used. The reasons for this are the relatively low levels of these PCBs in environmental samples, in addition to the fact that in several clean-up procedures these PCBs end up in the dioxin fraction and are easily run together with the dioxins in the same GC/MS run.

3.2 Sample Enrichment and Clean-up

The choice of the sample clean-up and enrichment procedure is dependent on many elements. The sample levels and matrixes determine the clean-up as well
Figure 5 Full-scan spectrum of a hexa-PCB in a whale sample. The spectrum was acquired at 70 eV over a mass range of 100–600 amu at a scan speed of 1 scan s$^{-1}$.

Figure 6 Full-scan spectrum of a hepta-PCB in a whale sample. The spectrum was acquired at 70 eV over a mass range of 100–600 amu at a scan speed of 1 scan s$^{-1}$. The typical molecular Cl$_7$ mass cluster, the loss of Cl to form a fragment containing Cl$_6$, and the typical loss of two chlorines resulting in a more abundant Cl$_5$ cluster are all shown.
as the detection technique used. The more selective the detection technique, the less laborious the sample clean-up that has to be performed on the sample extract. Generally, when using GC-based detection techniques, sample clean-up is necessary. The clean-up can be divided into three steps: an acid/base clean-up including a fat removal step; an open-column chromatographic step; and, for the detection of mono ortho or planar PCBs, a planar separation step on carbon is essential.

3.2.1 Acid/Base Clean-up/Fat Removal

Because PCBs are such stable compounds, rigorous clean-up schemes can be applied without risk of destroying the target compounds. The sample extract can thus be digested by a strong acid or base with relatively small analyte losses. Back-extraction with an organic solvent (hexane, methylene chloride) partitions the PCBs back to the organic phase while the fats are destroyed and other more polar interferences partition to the acid or base phase. Acid or base digestion is mainly used for large sample sizes or heavily contaminated samples. A more sophisticated approach involves the use of acid/base-modified silica. Activated silica is “loaded” with, for example, sulfuric acid or sodium/potassium hydroxide. Again, depending on the sample size, silica can be modified by 22% or 44% of acid (wt%). The use of combined acid/base/activated silica open-column chromatography in one single column is a commonly used clean-up procedure using hexane or a combination of hexane and methylene chloride as the elution solvent.

Other options for the removal of large amounts of fat or other large compounds are gel permeation chromatography (GPC) or dialysis using semipermeable membrane devices (SPMDs). Size-exclusion chromatography (SEC) or GPC is based on the stronger retention of smaller compounds as compared with macromolecules (fats, humic acids) in the 600–1500 amu range. In GPC the stationary phase is a hydrophobic gel (Styragel™, Bio-Beads™, Sephadex™) into which the smaller molecules can penetrate while the larger macromolecules are not retained. The large macromolecules therefore elute first, followed by the smaller molecules. By using model compounds or commercial PCB oil the GPC column can be calibrated using ultraviolet (UV) detection. GPC is widely used for the separation of PCBs and fat in biological samples and is well described in the literature.

SPMDs are based on the diffusion of the target compounds through a semipermeable membrane with a typical cut-off size of 10 Å (500 amu). A polyethylene tube.
Figure 8 SIR chromatogram of hexa-PCBs in a human sample. The (a) channel represents the $^{13}$C-labeled internal standard and recovery standard at mass 371.88, (b) represents the channel with the $m+2$ mass of the molecular chlorine cluster at mass 361.64, and the (c) channel shows the most abundant $m+4$ mass of the molecular chlorine cluster at 359.84. The most abundant hexa-PCBs in a human sample are marked by their Ballschmiter numbers (#153, #141, #138, #128/167, #156, #157).

is filled with the samples, sealed and placed in a column filled with pentane. Lipid removals are in the 90–99% range using two to three volumes of cyclopentane collected after 24 h of dialysis. The recoveries of the PCBs and pesticides in the combined dialysis fractions range from 88% to 98%. SPMDs have recently been used as sampling devices for PCBs in water, reflecting the bioaccumulating fraction of hydrophobic chemicals, using trioline within the polyethylene tube.

3.2.2 Open-column Chromatography

Open-column adsorption chromatography is the most common clean-up technique and is based on the differences in polarity, solubility and consequently partitioning between the stationary phase and the elution solvent. The affinity of PCBs and interfering compounds depends on the surface activity of the adsorbent and the solvent strength of the elution solvent. By using different adsorbent materials (silica, Florisil, alumina) which can be activated at different temperatures, clean-up procedures can be fine-tuned for specific applications. Open-column chromatography is used in many configurations and column sizes, with a wide variety of organic solvents (either alone or in combination). Before using a clean-up column, the column has to be calibrated. The elution volume in which the PCBs elute has to be determined, preferably with the real sample matrix present. Adsorbents used a relatively long time after activation, or even those from different batches, can become less active and thus should be calibrated again. Azulene, an aromatic dye, has been used to facilitate easy calibration of several adsorbents used for the clean-up of PCBs. Another precaution that should be taken when doing trace analysis is to check the adsorbent for PCB contamination. Several silicas have been reported to contain trace amounts of PCBs, and thus careful washing of the adsorbent with organic solvents is needed.

One of the most commonly used absorbents in clean-up procedures for PCBs is Florisil, a synthetic magnesium silicate. Normally Florisil is designed by the manufacturer to be activated at 650 °C and should be
stored at a temperature of 130 °C before use. Florisil\textsuperscript{30} is used both fully activated and 2–5% deactivated with water. Traditionally the elution solvent is an ethanol–diethyl ether (2:98) mixture, but the use of several other mixtures has been reported, including ether–petroleum and ethyl ether–hexane. More recently hexane–methylene chloride combinations or hexane alone have gained more popularity. Note that the different combinations and thus solvent strengths can change the elution patterns of PCBs and other compounds considerably.

As well as acid or base modified, granular silica can also be used activated or deactivated by applying small amounts of water. The hydroxyl groups of silica bind to the compounds applied and thus a separation on polarity is achieved. The PCBs interact with silica with basically the same strength and only minor separation of the PCBs due to size can be achieved on silica. In several procedures the “rough” silica clean-up is used before moving on to a more specific Florisil\textsuperscript{30}, alumina or carbon column. n-Hexane is usually used as the elution solvent, sometimes in combination with methylene chloride.

Alumina (Al\textsubscript{2}O\textsubscript{3}) or Al\textsubscript{2}O\textsubscript{x} is used in a wide variety from activity grade I (0% water) to V (15% water), also known as “super” AlO\textsubscript{x}. Alumina has gained its popularity as an adsorbent in “dioxin” analysis because it can be used to separate the more polar dioxins and furans from the less polar PCBs. When applied to an alumina column the PCBs are less well retained and typically elute with hexane or hexane with a small percentage of methylene chloride (2–5%), while the dioxins and furans need a stronger solvent such as methylene chloride or a 50% mixture of methylene chloride and hexane. In some special cases structural separation based on planarity of the PCBs has been achieved, but not as effectively as on a carbon column.

3.2.3 Carbon Column

Initially carbon (Fisher coconut charcoal) was used to separate PCBs from the DDT group of pesticides.\textsuperscript{35} The ability of active carbon (Darco-C\textsuperscript{36}) to separate on the number of chlorine atoms in the ortho position was then discovered.\textsuperscript{38} The prospect of using active carbon (PX-21\textsuperscript{39}) was later on fully exploited for the separation of the “bulk”, o-substituted PCBs and pesticides from the planar PCBs (#77, #126, #169) and dioxins.\textsuperscript{37} Both dioxins and non-o-PCBs can adapt a planar configuration. This results in a strong retention of these compounds on carbon and even strong solvents like methylene chloride cannot elute these planar compounds from a carbon column. After applying the sample to the active carbon column, nonplanar compounds can be eluted from the column with a mixture of hexane–methylene chloride. The dioxins and planar PCBs have to be eluted with an aromatic solvent (toluene). In some cases only back-elution of the column will result in the elution of the planar compounds in reasonable amounts of aromatic solvent. In the literature\textsuperscript{38} more than 34 different protocols are mentioned, using 10 different carrier materials. The majority of the methods use PX-21\textsuperscript{39}, or its successor AX-21\textsuperscript{39}, mixed with different carrier materials. Other commonly used carbon materials include Wako active carbon and Carbopack C\textsuperscript{39}. Problems with the reproducibility of the different active carbons have been observed and recently high-performance liquid chromatography (HPLC) columns have been introduced to obtain better results. Good separation between the planar and nonplanar PCBs was achieved on porous carbon gel (PCG) HPLC columns.\textsuperscript{39} Along with the establishment of TEFs for the mono-o-substituted PCBs (see Table 1), the interest in separation by the number of ortho chlorine atoms was revived. The separation on the classic PX-21\textsuperscript{39} was reported\textsuperscript{40} and in addition the isolation of the mono-o-substituted PCBs was successfully done using PX-21\textsuperscript{39} dispersed on an octodecylsilane HPLC column.\textsuperscript{41} This separation was also reported upon a PCG column.\textsuperscript{42}

Typically three fractions are obtained from the HPLC: a fraction with the pesticides and “bulk” PCBs, a fraction with the mono-o-PCBs and a fraction with the planar PCBs, dioxins and furans. In Figure 9 a typical clean-up protocol for a combined PCB and dioxin analysis is shown as an illustration of a fine-tuned clean-up procedure.

3.3 Extraction

The octanol–water partition coefficient (K\textsubscript{ow}) of the PCBs varies between 4.3 for the mono-substituted PCBs and 8.26 for the deca-substituted PCBs.\textsuperscript{43} This indicates a partition coefficient between the organic and the water phase of 10\textsuperscript{4}–10\textsuperscript{6}. This implies relatively easy extraction of PCBs from the water phase. Liquid–liquid extraction by shaking the water sample with an organic

![Figure 9](image-url)
Extraction cycles are performed at temperatures between above the boiling point of the extraction solvent. Pressurized, making it possible to perform extractions at higher temperatures. Basically the organic solvent is This technique is based on more efficient extraction agent (sodium sulfate) is one of the most commonly used extraction techniques. Soxhlet extraction can also be used. More recently solid-phase extraction (SPE) has been developed for large water samples, which are normally difficult to extract by traditional liquid–liquid extraction. In SPE the water is pumped through an adsorbent (XAD-2™, polyurethane foam, C18-silica) leaving the hydrophobic PCBs behind on the adsorbent. The PCBs are dissolved from the absorbent by an organic solvent. Care should be taken when the water contains particulate or organic matter. For solid samples Soxhlet extraction is the preferred method although other solvent extraction methods are known, e.g. centrifugation after mixing with an acetone–methylen chloride–hexane mixture, column extraction with organic solvents after mixing with sodium sulfate, or sonication with an organic solvent. During Soxhlet extraction a solvent is refluxed through a cooler where it condenses and drips back into a thimble containing the sample. This process continues until the thimble is filled to the top and liquid siphons into the round-bottom flask containing the extraction solvent in a heater. These cycles are continued during the extraction period (12–48 h) resulting in a very efficient extraction. Recently even more efficient extraction has been achieved using accelerated solvent extraction (ASE™). This technique is based on more efficient extraction at higher temperatures. Basically the organic solvent is pressurized, making it possible to perform extractions above the boiling point of the extraction solvent. Extraction cycles are performed at temperatures between 100 °C and 200 °C, resulting in short extraction times (10–20 min) and considerable reductions in solvent use. PCBs are found in the fat fraction of biological samples and extraction of the lipids is normally sufficient. Column extraction of the sample homogenized with a drying agent (sodium sulfate) is one of the most commonly used extraction techniques. Soxhlet extraction can also be used on biological sample homogenates. The lipid fraction is most easily extracted from body fluids and other liquid biological samples (for example milk) by liquid–liquid extraction.

4 RECENT DEVELOPMENTS IN ANALYTICAL METHODOLOGY

The analytical chemistry of PCBs and other environmental pollutants has changed enormously over the last 30 years and this development is expected to continue into the next century. In this section some recent developments are described which are still at a developmental stage but are expected to have an impact on the analysis of persistent organic pollutants (POPs), including PCBs, in the near future. One major issue that will be improved is the speed of analysis, as both sample extraction and sample clean-up are expected to become faster and more efficient. In general more information is demanded more quickly and more accurately. This will lead to a combination of congener-specific PCB analysis, and for example pesticide or brominated flame retardant analysis in one extraction. In addition a strong demand to reduce the usage of (chlorinated) organic solvents is foreseen. The same demand for speed of analysis will be focused on the gas chromatographic detection techniques and fast GC is expected to be incorporated in the routine analysis of a wide variety of POPs. In sections 4.1 and 4.2 two promising approaches are discussed in more detail as examples of recent developments in the analytical chemistry of PCBs.

4.1 Supercritical Fluid Extraction Coupled with Liquid Chromatography

4.1.1 Introduction to Supercritical Fluid Extraction

Solvents and gases under high pressures at elevated temperatures are becoming more and more important as extraction media in environmental analysis. The use of CO2 at supercritical conditions, with or without modifiers, has increased enormously for both biological and solid samples.44–46 In addition, extraction by organic solvents at elevated pressure and temperature has also recently been introduced as ASE™ or enhanced solvent extraction. Several organic solvents exhibit much better extraction efficiencies under pressure at higher temperatures. Which technique to use depends on the sample matrix and the compounds to be analyzed. An important consideration is how specific the extraction should be. ASE™ or enhanced solvent extraction is in most applications rather unspecific and extracts not only the target compounds but also many interfering compounds. Extracts obtained in this way often need further sample enrichment or sample clean-up. Supercritical fluid extraction (SFE) has the advantage that it can be made very specific by varying the temperature, pressure and the addition of different modifier concentrations. To find the optimum SFE extraction conditions for different sample matrices and target compounds, however, demands somewhat more developed methods. When these optimum conditions are established the advantages of using SFE are obvious and minimal clean-up and sample enrichment is needed. So, not only is the use of organic solvents during extraction
4.1.2 The Theory of Supercritical Fluid Extraction

A gas or a liquid becomes a supercritical fluid above the critical point in its temperature/pressure phase diagram (Figure 10). The critical temperature ($T_c$) and the critical pressure ($P_c$) define this point. In the supercritical state a substance is neither a gas nor a liquid. The properties of a supercritical fluid are therefore intermediate between those of the gas and the liquid phases. The density is comparable with that of a liquid whereas the viscosity is equivalent to that of a gas. As a consequence, the diffusion rate is somewhere in-between those of the liquid and the gas phases. Supercritical fluids can be compressed to almost the same density as a liquid, and thus show liquid-like solvation properties. With respect to extraction, a supercritical fluid has a higher diffusion rate than a liquid, while still exhibiting the solvation capacity of a liquid. Consequently the mass transfer kinetics are rapid, and by controlling the pressure and temperature the solvent strength can be adjusted. Optimization by changing the pressure and temperature, to achieve selective extraction, is thus possible.

4.1.3 Supercritical Fluid Extraction Instrumentation

Substantial improvements have been made in recent years in SFE instrumentation, going from home-made instruments to sophisticated commercial instruments with the convenience of autosamplers and computer operation. The instrumentation required is basically rather simple (Figure 11). A gas cylinder where liquid CO$_2$ is withdrawn from the bottom is connected to a pump where the liquid is compressed to the desired pressure. The gas is preheated to the extraction temperature in an oven in which the extraction vessel is placed. A restrictor placed after the extraction chamber controls the CO$_2$ flow and a variable pressure regulation system controls the pressure in the extraction vessel. Collection of the PCBs after expansion of the supercritical CO$_2$ can be done in a liquid or on a solid phase.

4.1.4 The Use of Supercritical Fluid Extraction in Polychlorinated Biphenyl Analysis

SFE is very suitable for the extraction of PCBs in a wide variety of samples. By optimizing the extraction conditions cleaner extracts are obtained which need less further sample clean-up. There is also the possibility of combining sample extraction and clean-up by utilizing the solid-phase trap for supercritical fluid extraction/liquid chromatography (SFE/LC). Excellent results have been achieved with direct injection of concentrated SFE extracts containing PCBs without further sample clean-up. The extraction of PCBs from soils, sediments, sewage sludge and absorbents has been successfully reported by a number of research groups.$^{47-50}$ Methods using SFE performed well in certification exercises for soil.$^{51}$ Successful SFE of PCBs from biological samples has also been reported upon in the literature.$^{52-55}$ The most encouraging approach is the combined POPs analysis using SFE/LC$^{56}$ or supercritical fluid extraction/gas chromatography/mass spectrometry (SFE/GC/MS).$^{57,58}$ In both procedures a large number of compounds were reported besides the PCBs, including dioxins, furans, DDT, chlordane and brominated flame retardants.

4.2 Gas Chromatography Coupled with Time-of-flight Mass Spectrometry

The sample preparation procedure, including both extraction and clean-up, has become more efficient due to the use of new extraction techniques.$^{46}$ By combining
extraction and clean-up using SFE/LC, the time required to produce an extract ready for GC/MS injection has been considerably reduced, from several days to only 20 min. When achieving such fast clean-up and extraction, suddenly GC/MS analysis becomes the bottleneck in the analytical process. The introduction of fast GC is a step in the right (“fast”) direction, but there are problems getting conventional mass spectrometers to achieve the very fast scanning times needed. Time-of-flight mass spectrometry (TOFMS) devices do not experience these kinds of problems and are able to scan more than 50 times s⁻¹, more than enough for fast GC applications. A schematic diagram of a time-of-flight mass spectrometer is given in Figure 12. In a TOFMS instrument operated in the EI mode, the ions are accelerated into the flight tube at a frequency of 36 kHz. After reflection from the ion mirror the ions can be measured at a rate of up to 100 scans min⁻¹. Figure 13 shows the reconstructed GC/MS runs of both the TOFMS and the quadrupole analysis of a human adipose tissue sample. The summation of mass channels 360, 394 and 318, corresponding to the masses for hexa-PCB, hepta-PCB and 1,1-dichloro-2,2-bis(p-chlorophenyl)ethylene respectively, is shown here. Figure 13 clearly illustrates the difference in analysis time between the GC/TOFMS run and the SIM quadrupole run. It takes less than 7 min to elute all compounds of interest and still achieve enough resolution to identify and quantify all PCBs and pesticides of interest in a human sample from the GC/TOFMS run with the fast GC. It is possible to quantify more than 30 different PCB congeners in a human sample above the detection limit. Combining SFE/LC as the sample extraction and pretreatment technique with GC/TOFMS analysis reduces the analysis time for screening of environmental pollutants from several days to less than 1 h. The fast analysis with a GC/TOFMS instrument, utilizing a “fast” GC column, still gives enough resolution of 30 PCBs because of the fast scanning times of a TOFMS instrument.

5 QUALITY ASSURANCE AND QUALITY CONTROL BY INTERNATIONAL COMPARISON

To illustrate the current analytical methodologies used in leading laboratories in Europe, Japan and the USA for analyzing PCBs in biological material, the reported methodologies from two recent interlaboratory studies are described in this section and Table 3. The summary is based on 14 laboratories within the IUPAC fish oil study and 19 laboratories in the WHO/EURO milk study. There is some overlap between the 33 participating laboratories, i.e. some of the laboratories took part in both studies. The main steps in the PCB analyses are summarized in Table 3: (a) extraction of the fat including the analytes, (b) quantitative determination of the amount of fat, (c) clean-up, i.e. isolation of the analytes from the fat and from other interfering components, (d) detection and (e) quantification of the analytes.

Some native standards used: $^{13}$C-PCB #22, 29, 72, 66, 104, 112, 155, 185, 196, 199 and 207
Isotope-labeled standards: $^{13}$C-PCB #28, 52, 101, 105, 118, 138, 153, 180, 194, 202

---

* Solvents used: $i$-octane (dilution), toluene (Soxhlet), hexane, diethyl ether, ethanol, acetone, cyclohexane, pentane (liquid or column) and CO$_2$ (SFE).
* In the IUPAC study the sample was pre-extracted and the total weight measured was used as fat weight.
* H$_2$SO$_4$ treatment most common.
* Column materials used: modified silica, alumina, Florisil™ and carbon.
* GC columns used (all capillary 30–60 m): Ultra 1™, Ultra 2™, DB-5™, SPB-5™, RTX-5™, DB-DIOX™, DB-17™, SPB-17™, DB-210™, SIL19-CB™, CP-SIL5™, CP-SIL8CB™, SPB-20™ and SPB-Octyl.
* MS technique: SIR, EI.
* In both studies referred to here individual concentrations of PCBs were to be reported.
Of the 14 laboratories in the IUPAC study 8 were found to have a standard deviation ($S_r$) of within-laboratory repeatability of $4$–$17\%$ for individual congeners, while the rest were within $45\%$. The standard deviation of between-laboratory reproducibility ($S_L$) was between $15\%$ and $48\%$ for nine of the labs, four of the labs were off by up to $80\%$ and one was $>100\%$ off. The following PCB congeners were most accurately determined in the fish oils: 28, 52, 66, 74, 101, 105, 114, 118, 128, 153, 156, 167, 170, 180 and 183. Other congeners were not included when calculating the standard deviations.

In reporting total PCB levels (also denoted sum of PCBs) in a biological sample several approaches can be used and will eventually result in greater deviations in the results generated in different laboratories than when reporting concentrations of single congeners. The comparison, for instance in trend studies, of total levels of PCBs reported in biological materials today compared with reports from the 1960s to the 1980s, based on quantification with Aroclor™ and other technical mixtures as standards, is a problem. Also the use of different quantification techniques and lack of documentation of more precise calculations make comparisons very difficult.

From the interlaboratory studies mentioned one can conclude that the state-of-the-art methodology today for PCB determination, as far as this is defined by most-used methodology, is one that uses a “very traditional” liquid extraction, followed by “traditional” open-column chromatography clean-up, and finally a “less traditional” detection and quantification step. (“Traditional” is used to indicate the progression in methodology since the early 1950s.) Further, in comparing results between different laboratories the reported PCB levels in the same sample can be assumed to have a standard deviation of less than $50\%$.

and combine rapidly, forming aromatic ring structures. Another mechanism of PAH formation is pyrolysis, the “cracking” of organic compounds, such as higher alkanes, forming radicals. These radicals combine and form condensed aromatic molecules. The final products of this procedure are those which are thermodynamically preferred.\(^2\)

1.3 Health, Biological and Environmental Hazards of Polycyclic Aromatic Hydrocarbons

Many of the PAH and PAC compounds are known carcinogens and/or mutagens. Among the first PAHs that were found to be carcinogenic in laboratory animals were dibenz[a,h]anthracene and benzo[a]pyrene.\(^3,4\) The carcinogenicity of PAHs depends upon activation by a class of enzymes, cytochromes P-450. When oxygen is added to PAHs by these enzymes, the product is an epoxide, which is a potent electrophile. The epoxide, generated inside the cell, can diffuse into the nucleus and react strongly with DNA, resulting in gene altering.\(^5\)

Some microorganisms have the ability to metabolize certain PAHs, e.g. benzo[a]pyrene, forming a mixture of metabolites. Some of these metabolites, epoxides for instance, are carcinogenic in higher organisms, but some derivatives are detoxified derivatives.\(^6\)

1.4 Environmental Occurrence of Polycyclic Aromatic Hydrocarbons

Since there are many processes of incomplete combustion and pyrolysis that favor production of PAHs, these pollutant compounds are abundantly encountered in the atmosphere, soil, and water. The occurrence of PAHs can be divided into two major categories. One involves natural processes such as forest burning, and the other category involves human-made procedures, e.g. aluminum production, wood burning, wood stove smoke, coal steam power plants, oil and natural gas combustion, and motor vehicle exhaust. Coal tars and petroleum residues, such as road and roofing asphalt, also contain and emit high levels of PAHs. The levels of PAHs in the atmosphere may often reach 20 µg m\(^{-3}\). These high concentrations are most likely encountered in polluted urban atmospheres and in areas of natural fires, such as forest fires. Coal furnace stack gas may contain over 1000 µg m\(^{-3}\) of PAHs and cigarette smoke contains almost 100 µg m\(^{-3}\) of PAHs. Owing to the low vapor pressure of many of the PAH compounds, they are most likely found in aerosols or condensed onto aerosol particles. PAHs are often adsorbed on soot particles. An important source of PAHs in urban environments is the diesel exhaust. The diesel engine is more economical than the gasoline engine, therefore it has become popular. The exhaust emission contains...
2 SAMPLING, PRETREATMENT AND EXTRACTION TECHNIQUES FOR POLYCYCLIC AROMATIC HYDROCARBONS

Conventional environmental sampling is based on the collection of the sample, followed by sample preparation, pretreatment and extraction, and finally analysis. These procedures have to be followed as a part of most standard analytical methods. However, recently developed analytical methods, which will be briefly discussed in the last section of this review, allow for direct analysis of environmental samples. It is hoped that these new techniques will avoid the time-consuming procedures of pretreatment or extraction.

2.1 Environmental Sampling of Polycyclic Aromatic Hydrocarbons

The goal of collecting environmental samples is to obtain a small fraction that reflects the properties of the evaluated population. The confidence in data quality generally depends on the number of samples and on the location and timing of sampling.⁷

2.1.1 Air Sampling

Air is comprised mainly of gas molecules. However, air also carries many organic compounds of environmental interest in aerosols. These compounds are usually found at low concentrations and may be distributed between two phases, solid–gas or liquid–gas. Low analyte concentration requires high sample volume, therefore a proper air sampling may become the bottleneck of airborne PAH analysis.

2.1.1.1 Sampling of Vapor Phase Polycyclic Aromatic Hydrocarbons

Steel canister or Teflon® bags are commonly used for collecting a measured volume of air. The air is passed through a solid sorbent that traps the organic compounds. The use of solid cyclodextrins (CDs) for extraction of vapor-phase PAHs from air is a well-established method. CDs are cyclic oligosaccharides which possess a hydrophilic exterior and a less polar interior cavity. This property enables extraction of PAHs by formation of inclusion complexes.¹³ Other types of solid sorbents are organic polymeric sorbents (e.g. Tenax), inorganic sorbents (e.g. silica gel and alumina), and carbon. Another technique for sampling volatile or unstable species is cryo-sampling, where the sample is condensed in a cryogenic trap. In this method, the total volume of sampled air can be calculated from the volume of the collected water.⁷

Another sampling method is passive monitoring, where the analyte is collected from air by diffusion and introduced into the monitoring device. This technique can not provide reliable information concerning the analyte concentration.

2.1.1.2 Sampling of Solid-phase Polycyclic Aromatic Hydrocarbons

As mentioned previously, because of the low vapor pressure of many PAH compounds, they are most likely found in aerosols or condensed onto aerosol particles.¹⁴ A proper analytical sampling of aerosols, which maintains the original chemical composition and does not introduce artifacts due to geometrical or morphological considerations, is a most challenging task. Airborne particulate matter is usually sampled using filtration techniques. Porous membrane filters (e.g. cellulose esters and Teflon®), and fibrous filters (e.g. cellulose fibers and glass fibers) are commonly used for PAH sampling. During the filtration process, particles depart from the air stream, collide with the filter and attach to it. Several mechanisms are responsible for deposition of aerosols on filter-based samplers, including interception, inertial impaction, diffussion, gravitational settling, and electrostatic attraction.¹⁵

The above sampling methods are well established; nevertheless, they are not free of artifacts. Among these pitfalls are changes in particle size distribution due...
to electrostatic deposition or vaporization and artifacts caused by various interactions. The development of online and in situ sampling, followed by direct analysis, has the potential to avoid artifacts in airborne PAH detection.\(^\text{16}\)

Another recently reported sampling technique, suitable for both PAH vapor and airborne particulates, is based on a renewable water microdroplet.\(^\text{17}\) In this method, a water microdroplet comes in contact with ambient air and quasi-equilibrium conditions are achieved. The contaminated droplet can be analyzed for PAH compounds, and a fresh one is readily produced for the next sampling cycle.

Meteorological effects such as wind velocity, wind direction, temperature and atmospheric pressure should also be considered while sampling.\(^\text{7}\) Such information may affect the sampling validation on one hand, and may provide useful insight to the analytical results, on the other.

2.1.2 Water Sampling

Water sampling for PAH analysis depends on the type of water under consideration, for instance, surface waters (e.g., rivers, lakes), groundwater, or wastewater. Many of these water types require particular sampling procedures and treatment. Another difficulty in water sampling is the heterogeneity of water, both spatially and temporally. Organic materials containing PAHs can either float on the water surface, sink to the bottom or be suspended in the flow, depending on their weight and density.\(^\text{7}\) Many additional problems need to be considered for accurate PAH sampling.

The relevant concentration of dissolved individual PAH compounds varies between sub-parts per trillion (pg g\(^{-1}\)) for groundwater, to the order of parts per million (µg g\(^{-1}\)) for highly contaminated water. The low PAH concentration samples require application of preconcentration techniques prior to analysis. Furthermore, analysis of low PAH concentrations can lead to serious errors due to analyte losses or contamination in the sampling process. PAHs can be deposited on any surface with which they come in contact during sampling and extraction.\(^\text{10}\)

It was found that PAH solutions at the ppb concentration level exhibited 80% PAH adsorption loss after 4 h of stirring in a glass container.\(^\text{18}\) Other PAH sampling losses are related to chemical or biological degradation in the vessels. Therefore, water samples must be held in the dark, at subzero temperature in glass containers, pretreated for removing any organic traces. The best way of avoiding some of these sampling problems is the direct sampling into the extraction vessel, followed by extraction steps, without any delay.\(^\text{10}\)

Solid adsorbents such as Tenax and Amberlite resin are convenient for sampling large volumes of water. However, this procedure leads to the loss of the volatile compounds. Liquid extraction of PAHs from water systems can also be performed using an organic solvent that could easily be separated from the water, e.g., methylene chloride.\(^\text{10}\)

2.1.3 Soil Sampling

The heterogeneity of soil along with the fact that PAHs concentration in soil may depend on sampling depths and may possess various distributions, make soil sampling very complicated.\(^\text{7}\) No simple sampling procedure is prescribed, but, it is usually recommended that soil samples are preserved by freeze-drying, followed by graining and sieving.

2.2 Extraction Methods

One of the most significant difficulties in analysis of environmental samples is related to the complexity of the matrix. Environmental samples are usually composed of numerous analytes and interfering matrix components. Extractions are performed in order to separate the analyte from the interference.

2.2.1 Soxhlet Extraction

Conventional extraction of PAHs involves different organic solvents, e.g., hexane, acetone, methanol, acetonitrile, toluene. An efficient method of extraction of PAHs using organic solvents is the Soxhlet extraction, in which the solvent is vaporized in a distillation flask, rises through an exterior tube to a condenser and then liquefies by cooling. The liquid drops onto a porous vessel containing the sample. The solution of the solvent and the dissolved matter is drained back into the distillation flask. This circulation is usually carried out overnight, and finally, the solution containing the extracted matter is collected. Automatic devices for speeding up the extraction are available. Soxhlet extraction of PAHs usually serves as a reference for new extraction techniques.

2.2.2 Alkaline Saponification

Alkaline saponification is an effective extraction method based on hydrolysis of esters, using KOH/methanol mixture. This method is especially useful for PAH extraction from contaminated soil samples. One of the major problems in PAH extraction from soil is related to the fact that PAH molecules might be strongly bounded to the soil matrix (humic polymer).\(^\text{19}\) Therefore, conventional organic solvent extraction is not entirely effective, and a more rigid extraction procedure is necessary in these cases. Application of saponification as an extraction tool, in addition to conventional
organic solvent extraction, succeeded in recovering a significant higher amount of PAH compounds from soil, comparing to the amount obtained by organic solvent extraction alone.\textsuperscript{(19–21)} These findings were attributed to cleavage of ester bonds, which form parts of the humic macromolecules. This process results in releasing PAH molecules trapped in the humic polymer.\textsuperscript{(19)}

2.2.3 Sonication

Sonication is another traditional extraction technique, based on cold liquid–solid extraction. Originally, mechanical shaking was applied and, later, better results were accomplished by ultrasonic treatment. Nevertheless, the recoveries of PAHs extracted by sonication are lower than those obtained by other techniques, e.g. Soxhlet extraction.\textsuperscript{(22)}

Recently, several other extraction techniques have been developed for the determination of PAHs in environmental matrices such as solids and sediments. These techniques are supposed to improve recoveries of PAHs and to reduce both the extraction time and the amount of solvent used. Among these techniques are supercritical fluid extraction (SFE), accelerated solvent extraction (ASE), and microwave-assisted extraction (MAE), which will briefly be discussed in the following sections.

2.2.4 Supercritical Fluid Extraction

SFE is a highly promising alternative to conventional Soxhlet extraction of environmental samples. Heating a gas above its critical temperature or compressing a liquid above its critical pressure produces supercritical fluids. Under these conditions, the molar volume is the same whether the original form was a liquid or a gas. Due to its physical properties, i.e. low critical pressure and temperature, CO\textsubscript{2} has become a major solvent for SFE. The properties of supercritical fluids provide some advantages for analytical extractions. Supercritical fluids may have solvating powers similar to liquid organic solvents, but with higher diffusivity, lower viscosity, and lower surface tension. The solvating power can be adjusted by changing the pressure or temperature, or by adding modifiers, e.g. methanol, methane chloride and toluene to the supercritical fluid. Further advantages of using supercritical fluids for environmental sample pretreatment are the low cost and the facts that they are contaminant free. Moreover, their safe disposal is less expensive than the cost of organic solvents.\textsuperscript{(23)}

SFE has been used to extract PAHs from solid environmental samples, including complex matrices and analytes. Attempts were made to investigate the effects of various factors affecting PAH recoveries in SFE, such as matrix characteristics, analytes, extraction fluid, modifiers, temperature and pressure.\textsuperscript{(22,24–30)} It was found that the PAH recoveries from various matrices differ significantly due to the interactions between the matrix, the analytes and the supercritical fluid. The effects of matrix characteristics on the recoveries of five PAHs (anthracene, pyrene, chrysene, benzo[a]pyrene, and perylene) were recently investigated. The PAHs were adsorbed on two series of adsorbent matrices, i.e. polystyrene divinylbenzene copolymer (XAD resin) and silica. It was found that the recoveries of the PAHs were relatively higher if they were extracted from a matrix of a smaller surface area and larger pore size. Considering the analyte–matrix interactions, for a given matrix, it was reported that the PAH recoveries decreased with the increasing molecular weight. In addition, the analyte desorption improved when the temperature was increased.\textsuperscript{(25)}

The effectiveness of SFE of different PAHs from natural matrix standard reference materials (SRMs), e.g. water sediments, diesel particles, and urban dust, were also studied. The results revealed the limitation of SFE. The recoveries of specific compounds extracted from these samples were matrix dependent. The lowest recoveries of high-molecular-weight PAHs were obtained from diesel particles.\textsuperscript{(25)} In these cases the recovery figures were much lower (<20%) than the Soxhlet results.

Optimization of SFE of PAHs from real soil samples were also studied and compared to Soxhlet extraction. It was established that low-molecular-weight PAHs (in the range of 128–178 Da) can be extracted with pure CO\textsubscript{2}, while high molecular weight PAHs (202–278 Da) can only be extracted using modifiers added to CO\textsubscript{2}. A higher temperature was found to improve recoveries of all PAHs under USEPA control. The addition of small amount of water also improved extractability of these PAHs because of the swelling effect of the matrix.\textsuperscript{(26)} SFE was accepted as an official method by the USEPA.\textsuperscript{(31)}

2.2.5 Accelerated Solvent Extraction

ASE uses a conventional solvent up to 200 °C as an extraction medium. At high temperatures the solvating ability of certain solvents increases. As a result, PAH recoveries also increase due to changes in diffusion coefficients. In this method, extraction is performed under pressure (0.3–20 kPa), in order to keep the solvent in the liquid phase. Under these conditions, extraction kinetics and desorption of the analyte from the matrix are significantly enhanced. As far as extraction of high molecular weight PAHs from diesel materials was concerned, ASE was proved as an efficient method, compared to both Soxhlet extraction and SFE.\textsuperscript{(22,25,32)} The USEPA also accepted the ASE as an official extraction method for PAHs.\textsuperscript{(33)}
2.2.6 Microwave-assisted Extraction

Microwave energy is used as a heat source that is capable of heating the whole sample simultaneously without heating the vessel. In addition, in a sealed apparatus, the solvent may reach a higher boiling point. The combination of the higher boiling point and the rapid heating increases extraction efficiency and reduces the overall extraction time. Microwave energy was used for extraction of PAHs from contaminated soil and sediment samples. The results indicate that in many cases MAE is an achievable alternative to the traditional Soxhlet and sonication techniques.\(^{34,35}\)

2.3 Clean-up Techniques

The extraction techniques (section 2.2) are optimized for providing a high PAH recovery. Therefore the extract solution may contain a significant amount of side materials (co-extracts), such as other organic compounds. Clean-up methods for PAHs are applied to extract solutions in order to eliminate sample interference. The most commonly used clean-up techniques for PAHs are briefly discussed in the following sections.

2.3.1 Solid-phase Extraction Clean-up

Liquid adsorption chromatography for PAH clean-up is performed in normal phase using alumina (USEPA method 3611),\(^{36}\) Florisil\(^{®}\) (USEPA method 3620),\(^{37}\) and silica gel (USEPA method 3630).\(^{38}\) These columns may be prepared in the laboratory or solid-phase extraction (SPE) cartridges can be used.\(^{39}\) SPE using a Florisil\(^{®}\) column and dichloromethane was utilized for clean-up of PAHs in sewage sludge and soils.\(^{40}\) SPE using silica column and methanol–dichloromethane (2:3) was also applied for clean-up of PAHs in sediments.\(^{41}\)

2.3.2 Gel Permeation Chromatography Clean-up

Gel permeation chromatography (GPC), also called size-exclusion chromatography (SEC), utilizes porous particles in order to separate molecules by their different size. This method is capable of separating high molecular-weight materials from the sample. The GPC method was approved by the USEPA (method 3640)\(^{42}\) and was recommended for PAH clean-up.

2.3.3 Acid–Base Partitioning Clean-up

The acid–base partitioning clean-up method is based on liquid–liquid partitioning for separating acid analytes, e.g. organic acids and phenols, from basic or neutral analytes such as PAH compounds, using a proper pH adjustment. The solvent extract (from a prior extraction procedure) is shaken with strongly basic water. The acid analytes partition into the aqeous layer, whereas the basic and natural compounds stay in the organic solvent. The latter fraction, containing the PAH compounds, is concentrated and is then ready for further clean-up or analysis. This method was also approved by the USEPA as a clean-up method (method 3640).\(^{43}\)

3 SEPARATION AND ANALYSIS OF POLYCYCLIC AROMATIC HYDROCARBONS

3.1 Gas and Liquid Chromatographic Techniques

PAHs are routinely analyzed by chromatographic procedures. Two major types of chromatography are commonly used, namely, gas chromatography (GC) and high-performance liquid chromatography (HPLC). GC is most useful for smaller PAH molecules, because they are generally volatile. HPLC is suitable for high molecular weight or nonvolatile PAHs. Generally, GC is used for PAHs of up to 24 carbons, whereas HPLC can be used for PAHs as small as naphthalene. The upper limit for HPLC is the condensed PAHs with 38 carbons (13 rings).\(^{44}\) Actually, the basic requirement for HPLC analysis is that the sample is soluble in the mobile phase, and many PAHs fulfill this simple requirement.

3.1.1 Gas Chromatography

The high resolution and short analysis times of capillary GC have made it the most popular analytical technique for PAHs. Capillary columns, with resolutions of several hundred thousand, can separate extremely complex samples such as tars and oils. The high resolution is especially needed in environmental PAH analysis due to the extreme complexity of most samples. These samples may contain many types of PAH compounds and, sometimes, also several isomers.\(^{44}\)

3.1.1.1 The Stationary Phase

The stationary phases in capillary GC was initially statically coated onto the column walls. These phases were thermally unstable at high temperatures. This limited their application in separation of low-molecular-weight PAHs. This limitation was overcome by the development of cross-linked polymeric or chemically bonded GC phases. These stationary phases are thermally stable (up to more than 100 °C), more reproducible, and more uniformly coated. In many cases, the GC separation of PAHs is very difficult because chemical affinities and boiling points of many PAH isomers are very similar. Sometimes the three-dimensional (3-D) structure of some isomers is slightly different and GC separation is possible due to stationary phases capable of
“molecular shape” differentiation. Liquid–crystalline phases have been shown to provide such capabilities.

A significant advancement in this field was achieved by coupling liquid–crystalline to a stable polysiloxane polymer, which made the synthesis of bound liquid–crystalline possible. Liquid–crystalline phases can separate the PAHs by their molecular shapes, since their separation is based on permeation of the PAH molecules between the layered phase. Correlations between various PAH topological and geometrical parameters have been studied and reported.

3.1.1.2 Gas Chromatography Detectors for Analysis of Polycyclic Aromatic Hydrocarbons

The mass spectrometer (MS) is a most widely used GC detector for PAH analysis. MS is used to determine molecular weights, and also some structural information on the analyzed PAHs. The fragmentation of PAH compounds may provide valuable information about PAH isomers present in the sample.

Fourier transform infrared (FTIR) spectrometers can also be coupled to GC for PAH detection and provide a high sensitivity. FTIR was found to be a powerful tool for the determination of various compounds of environmental interest. For example, this detection technique was successful in determining fluoren-9-ones in diesel particulates, while nitrogen-containing species were erroneously suggested by the GC/MS technique.

Although GC detection methods based on absorbance or fluorescence are generally sensitive and somewhat selective, they are not popular for PAH analysis. The reason is the technical difficulty of maintaining these compounds in the gas phase during detection on the one hand and the lack of gas phase reference spectra on the other.

Atomic emission spectroscopic detectors are sometimes applied for monitoring the atomic emission of individual elements such as nitrogen, sulfur and oxygen in PAH derivatives or in PACs. For instance, this method was applied for the quantification of polycyclic aromatic sulfur heterocycles (PASHs) in several SRMs from the National Institute of Standards and Technology (NIST), namely, SRM 1597, coal tar; 1580, shale oil; and 1582, crude oil. In this case it was shown that due to the co-elution problem of some PAHs (e.g. phenanthrene) along with other PASHs (e.g. dibenzothiophene and naphthothiophene), the NIST concentration figures were too high. The flame ionization detector (FID), which is the most common GC detector, is not of great use for PAH detection, because of its universality.

3.1.2 High-performance Liquid Chromatography

Although GC resolution is much better than that of HPLC, the larger nonvolatile or thermally unstable PAHs cannot be analyzed using GC techniques. These compounds can be separated only by HPLC. The smaller (nonpolar) PAHs are soluble in the weak normal-phase solvents such as n-hexane or in the weak reversed-phase solvents such as methanol and acetonitrile. PAHs that are less soluble in these solvents can generally be dissolved in stronger solvents such as dichloromethane, ethyl acetate, or tetrahydrofuran (THF). Mixing of solvents and solvent gradients are often carried out in order to achieve better separation.

The variety of mobile phase solvents, which can be applied in HPLC separations, makes this method suitable for environmental samples containing a large number of different PAH molecules. Other HPLC parameters, such as temperature gradient and variations in the stationary phase, also improves PAH separation.

Generally, two HPLC techniques are applied: the normal phase and the reverse phase. Normal-phase separation is based on hydrogen bonding and acid–base interactions between the silica (stationary phase) and the sample molecules. Another type of normal-phase HPLC applies alumina and derivatized silica (e.g. amino-, cyano-, phenyl-silica) as stationary phase.

Separation is based on polarizability and induction effects between the stationary phase and the sample molecules. The less polar PAHs elute before the more polar PAHs (nitrogen-containing PACs, for instance). This technique can be applied for separating PAHs by their aromatic ring number, or more accurately, by their \( \pi \)-electron number. The stronger the interaction between the analyte’s \( \pi \)-electrons and the polar stationary phase molecules is, the longer the retention times are. Therefore, the planarity of unsubstituted PAH compounds directly affect their retention times. Planar PAH isomers are retained longer than the non-planar ones.

Another factor affecting retention time of planar PAHs is their geometrical characteristic: the isomer with a longer molecular axis (i.e. one with a higher length to breadth ratio (L/B)), has a longer retention time. The reason is, again, the interaction extent of the analyte molecules and the polar-bonded phase.

Substituent groups also affect retention times: alkyl chains reduce the retention of PAHs relative to unsubstituted PAHs, probably due to a shielding effect, which reduces the interaction between the \( \pi \)-electrons and the polar-bonded phase. Cycloalkane substituents, on the other hand, increase retention times of PAHs, presumably due to a polarity increase.

Separations of PAHs are also carried out by the reverse-phase chromatographic technique. Here, the separation utilizes a nonpolar bonded phase and a polar solvent. The separation of PAHs can be performed using monomeric or polymeric bonded phases. Monomeric
phases are composed of bonded alkyl-substituted siloxane, while polymeric phases are based on bonded alkyl-substituted polysiloxane. Monomeric-phase based separations differentiate the number of carbon atoms in the analyte molecules. The polymeric phases, however, are usually very structured and organized, and therefore, separate PAHs by their 3-D shapes. These properties result in an efficient isomeric separation.

The L/B ratio and planarity of PAHs affect the retention times as well. PAHs with larger L/B ratio retain longer both in monomeric and polymeric bonded phases. Octadecylsilyl-bonded silica gel (C$_{18}$ column) reverse-phase chromatography is commonly used for PAH separation.

Shape selective retention of PAHs by applying other types of stationary phases, were reported. Metalloprotoporphyrins covalently bonded to silica were examined as stationary phases for reverse-phase HPLC separation of PAHs. The results showed very good shape selectivity for planar PAHs over nonplanar ones (Figure 2). The retention mechanism is believed to be primarily due to face-to-face $\pi$-interactions.

The retention behavior of PAHs on acridin derivative (dodecylacridinium) stationary phase of reverse-phase HPLC was also examined. It was reported that nonplanar PAHs exhibited smaller retention times relative to the figures obtained using octadecylsilyle-bonded silica gel. These results indicate that interactions between PAHs and the acridinyl ring dominate the PAH retention. In addition, the preferential retention of planar PAHs, rather than nonplanar ones, is attributed to the stronger interaction of the former with the acridinyl ring of the stationary phase.

Recent investigations succeeded in shortening HPLC analysis times and obtaining better information. Rapid and highly resolved separation (700 000 theoretical plates per m) of the 16 PAHs under USEPA control, was achieved by applying capillary electrochromatography. In this case, 28 kV was applied to a column packed with 1.5-µm octadecylsilica particles, using a mobile phase with low conductivity (acetonitrile mixed with sodium tetraborate). A sample containing all 16 PAHs was separated isocratically in less than 10 min.

A mathematical model for fast determination of the breakthrough volumes of PAHs was also developed. This procedure was applied for calculating the breakthrough volumes of 15 PAHs in a C$_{18}$ preconcentration column, for aqueous solutions containing 10% acetonitrile as organic modifier. This method is particularly useful for the less polar PAHs that have high breakthrough volumes (e.g. benzo[a]pyrene and benz[a]anthracene).

The HPLC detectors applied for PAH analyses are required to differentiate PAHs from other compounds and to differentiate PAHs and PAH isomers as well. Therefore, the most commonly used detectors for HPLC analyses of PAHs are UV absorbance and fluorescence detectors. The energies corresponding to the electronic transitions in PAH molecules are determined by their $\pi$-electrons, thus, the electronic spectra (UV absorbance and fluorescence) of PAHs are usually more featured than other organic species. The details of the electronic transitions are governed by the size and shape of the PAH compounds.

During the last few years the PAH separation by the HPLC technique has been greatly improved by multichannel detectors such as diode arrays and charge-coupled devices (CCDs). When these detectors are applied, the spectrally resolved transmitted or emitted light is simultaneously detected, providing a full spectrum of the analyte at any time. The full spectrum of PAHs, in addition to the retention time, is a valuable tool for PAH analysis.

Fast scanning fluorescence spectrometry detection for HPLC may also provide full spectral information of PAHs. Although spectral data are not collected simultaneously, in most cases the scanning time is adequate for unperturbed results. The combination of this method with 3-D multivariate calibration, based on retention time, emission wavelengths, and fluorescence

![Figure 2](image-url)
intensity, has provided successful analysis of PAHs in water samples.\(^{56}\)

Several fluorescence-based detection systems are coupled to HPLC for PAH analysis. Owing to reduced background, the sensitivity of fluorescence detection is very high, on the order of ppb. The sensitivity can be improved by up to two orders of magnitude when a laser is used as the excitation source.\(^{63}\) An ultraviolet laser-induced fluorescence (UV/LIF) detection system was applied for PAH analysis by HPLC and improved sensitivity and selectivity were reported.\(^{57}\)

Time-resolved laser-induced fluorescence, where fluorescence lifetimes are measured in addition to the fluorescence spectra, was successfully applied to identification of PAH isomers following HPLC separation.\(^{64}\) The identification principle takes into account the fact that isomers of a similar structure and spectra may differ in their fluorescence lifetimes. Nevertheless, since fluorescence lifetimes depend on the solvent used, appropriate standards must be available for identification of unknown peaks.\(^{44}\)

As previously mentioned, mass spectrometry provides a powerful detection tool for HPLC analysis. Indeed, HPLC/MS has been applied to a variety of PACs, providing informative fragmentation patterns. Although this technique is well established for routine laboratory operation, it still suffers from some inherent problems concerning the connection between the HPLC exit and the vacuum system of the MS.\(^{44}\) Therefore, HPLC/MS is currently not suitable for fast environmental surveys.

### 3.1.3 Other Techniques

Since PAHs constitute a large class of uncharged compounds, various separation techniques have been developed by inducing selective interactions between PAHs and charged additives. The most common technique is the micellar electrokinetic chromatography, in which separation is based on the partitioning of solutes into charged micelles, containing hydrophobic cores.\(^{65}\) This method was applied to PAH separation using both cationic and anionic micelles.\(^{66}\) Although successful separations were reported, it was found that the binding of PAHs to the micelle core was so strong, that selectivity could barely be achieved. Moreover, this method suffers from the instability of the micelles, which may be encountered in some experimental conditions.

Capillary electrophoresis (CE) is a separation technique of high efficiency, which is based on the differences in the abilities of charged compounds to migrate in an electric field. CE was successfully applied for separation of PAHs, by using charged CD derivatives, without the presence of micelles and based solely on the formation of inclusion complexes.\(^{67,68}\) The use of nonaqueous media for electrokinetic chromatography of PAHs is a promising alternative to aqueous solutions. This is due to the better solubility of PAHs in organic solvents. Moreover, certain organic solvents allow for application of higher electric field intensities and higher ionic strengths. Recently, separation of PAHs by nonaqueous CE was successfully performed using charge transfer (CT) complexation with planar organic cations (2,4,6-triphenylpyrylium ion and tropylium ion). It was reported that 2,4,6-triphenylpyrylium separates PAHs primarily according to their size, whereas for tropylium ion, separation is based on both PAH size and shape.\(^{69}\)

### 3.2 Optical Methods

#### 3.2.1 Ultraviolet/Visible Absorption Spectroscopy

Ultraviolet/visible (UV/VIS) absorption spectroscopy is a simple and useful tool for PAH identification purposes. The spectral information can be enhanced and improved by application of low-temperature UV/VIS absorption spectroscopy. One of the most useful applications of this method utilizes the Shpol’skii effect in an appropriate solvent type at very low temperature (4 K).

Derivative spectroscopy is another method for obtaining reach-structured spectral information, which is useful for PAH identification purposes. Although the use of derivative spectroscopy decreases the signal-to-noise ratio, it may improve the detection of spectral bands in a broad background, or of shoulders in a broad main band. The combination of a low-temperature technique and derivative spectroscopy yields quite characteristic spectra that can be used for identification of PAHs in complex mixtures such as environmental samples.\(^{70}\)

Absorption spectroscopy, as a whole, suffers of low sensitivity. Therefore probably the most commonly used application of UV absorption spectroscopy in PAH analysis is for HPLC detection systems (as described in section 3.1.2).

#### 3.2.2 Fluorescence Spectrometry

Luminescence spectroscopic techniques are widely recognized as excellent analytical tools, especially due to their high inherent sensitivity (zero-background measurements). Many PAH compounds possess strong fluorescence; therefore, several analytical techniques based on this property were developed.\(^{71}\)

Unfortunately, the fluorescence spectra of different PAHs present in an environmental sample often overlap. Therefore, identification and quantification of PAHs are not possible under these conditions. However, one can still perform chromatographic separation of a PAH mixture, prior to the fluorimetric analysis of the individual compounds.
Various methods have been developed in order to reduce the spectral overlap and to improve the quality of the information obtained by fluorescence analysis of environmental samples. Among these methods are synchronous fluorescence spectrometry (SFS), full excitation–emission fluorescence spectrometry (EEM), Shpol’skii spectroscopy (SS), laser-induced fluorimetry (LIF), time-resolved laser-induced fluorimetry (TRLIF), and multivariate calibration methods combined with fluorimetry. The applications of these techniques to environmental PAH analysis are briefly discussed in the following.

3.2.2.1 Synchronous Fluorescence Spectrometry

In conventional fluorescence spectroscopy, the emission spectrum is monitored by scanning the emission wavelength ($\lambda_{em}$), while the excitation wavelength ($\lambda_{ex}$) is fixed. The excitation spectrum is obtained by scanning $\lambda_{ex}$ at a fixed $\lambda_{em}$. However, in SFS, $\lambda_{ex}$ and $\lambda_{em}$ are simultaneously varied while the wavelength interval $\Delta (\lambda_{em} - \lambda_{ex})$ is kept constant. Theoretically, when a small wavelength interval is selected, synchronous fluorescence excitation analysis provides only one spectral peak for each PAH compound in the analyzed sample. Therefore, the synchronous fluorescence technique is often regarded as spectroscopic chromatography.\(^{(70)}\)

Several environmental applications of this powerful technique were suggested. Of special interest is the determination of several PAHs in spiked natural water samples, at concentration levels of a few ng/ml. This rather demanding task was successfully accomplished by combining synchronous fluorescence and multivariate calibration methods.\(^{(71)}\)

3.2.2.2 Full Excitation–Emission Fluorescence Spectrometry

The main advantage of full EEM is that the two-dimensional (2-D) information obtained can be used for resolution of PAH mixtures. Usually, chemometric techniques are required for a proper data analysis, and quite often only separation of PAH families (rather than individual compounds) is possible.

Better results are obtained for simple PAH mixtures. The application of EEM for identification and quantification of PAHs in simple mixtures was accomplished in several laboratories.\(^{(72–76)}\) In more complicated cases, such as analysis of samples containing 10 different PAHs, a combination of EEM and multivariate calibration methods was required for obtaining successful results.\(^{(77)}\)

3.2.2.3 Shpol’skii Spectroscopy

It is well known that broad-banded spectra are observed from compounds in condensed liquid and solid phases. This is a result of several effects, one of which is the inhomogeneous line broadening, i.e. each analyte molecule experiences a different influence from its surrounding solvent cage. This causes a slightly different Jablonski diagram for each analyte molecule. The overall spectrum is described as a Gaussian distribution of narrow lines with a total bandwidth of typically several hundreds per cm for each transition. The Shpol’skii effect is the spectral line narrowing. The reduction of the inhomogeneous line broadening can be accomplished by using an appropriate organic solvent at very low temperatures. The Shpol’skii effect is based on the geometric relationship between the organic solvent, i.e. the host molecules, and the PAH molecules, as shown in Figure 3.\(^{(78)}\)

It is believed that the narrow banded spectra are obtained by isolated molecules, trapped in the matrix during the cooling procedure and substituting one or more of the solvent molecules in the polycrystalline lattice.\(^{(78)}\)

Ariese\(^{(79)}\) demonstrated the power of SS by comparing the emission spectra of benzo[k]fluoranthene at room temperature (Figure 4a), spectrum and at 26 K (Figure 4b), spectrum. It is evident that the latter spectrum provides detailed information about the vibration levels of the electronic ground state.

The highly characteristic Shpol’skii spectra are suitable for qualitative and quantitative purposes in analytical and environmental chemistry. Actually many investigations showed that both conventional and laser excited SS can be successfully applied to the determination of PAHs in environmental samples.\(^{(80–83)}\)

---

3.2.3 Laser-induced Fluorimetry and Time-resolved Laser-induced Fluorimetry

Laser-induced fluorimetry (LIF) has been widely recognized as a standard technique for monitoring molecular species at very low concentrations. In this method a tunable source of laser light of narrow spectral bandwidth is brought into resonance with an electronic transition to an exited level. The measured fluorescence signal originates from the spontaneous radiation decay. Among the most important advantages of the LIF technique in PAH analysis are its high sensitivity and its power in probing various environments, even hostile ones such as flames. Additional analytical advantages are attributed to the possibility of applying pulsed lasers to on-line time resolved measurements. Optical fibers and various waveguides have largely contributed to LIF applications where remote sensing measurements are concerned. LIF techniques have already been coupled to many detection systems and analytical instruments such as mass spectrometry, chromatography, plasma ionization and laser induced breakdown spectroscopy. (These methods and their applications to environmental PAH analysis are briefly discussed here.)

An important factor that directly affects all on-line environmental analyses by spectroscopic techniques, is related to the homogeneity of the sample. Actually, all environmental samples are not homogeneous, although this fact is commonly ignored. For instance, environmental water is not homogeneous due to persistent hydrosols or microparticulates. Nevertheless, proper filtration and sample pretreatment are not possible in on-line applications; therefore analytical techniques that can be applied under such ambient conditions are of considerable importance. The effects of suspended materials on laser induced fluorescence of PAH molecules and its analytical performance, were recently investigated. The particle’s overall mass, light scattering and absorbing coefficients and particle size distributions were shown to effect fluorescence intensity of PAH in aqueous solutions. However, it was pointed out that a proper model can take into account all these effects and allow for reasonable PAH analysis.

On-line LIF and TRLIF were also evaluated for analysis of PAH contaminated aerosols. The experimental set-up used for this purpose (shown schematically in Figure 5) consisted of a fast nitrogen laser for fluorescence excitation, a monochromator for spectral detection and an oscilloscope for temporal resolution. Remote analysis was carried out via quartz optical fibers. Detection limits of 100 ng pyrene per m³ were achieved by using this set-up.

3.2.4 Phosphorescence Spectrometry

Several PAH molecules emit phosphorescence radiation and this characteristic can be utilized for analytical purposes. It is well known that the inherent phosphorescence quantum yield of PAHs can be enhanced by external heavy-atom perturbers. This method was originally developed for improving sensitivity and selectivity of low-temperature phosphorescence. However, phosphorescence enhancement by heavy atoms (e.g. thallium(I) acetate, lead(II) acetate) is also successfully used for room-temperature phosphorescence spectrometry (RTP). Unlike the low-temperature phosphorescence techniques, sample preparation for the RTP measurements is very simple and does not require cryogenic equipment. Therefore, this method is readily applied to PAH analysis.

The most simple and common RTP method is solid-surface room-temperature phosphorescence spectrometry (SSRTP), which has become a well-established method for analysis of environmental samples containing PAH compounds. A solid support is often required for SSRTP analysis. Among the solid supports used are silica gel, sodium acetate, and cellulose. Cellulose, and particularly filter paper, is the most convenient, inexpensive, and common substance for SSRTP.

It was found that the sensitivity of the SSRTP method could be considerably improved by applying a laser for excitation. Application of laser-induced SSRTP (nitrogen laser–pumped dye laser), with thallium(I) acetate as a phosphorescence enhancer, provided picogram limits of detection for several PAH compounds (phenanthrene, pyrene, benzo[g,h,i]perylene, chrysene, coronene, and 1,2-benzofluorone).
Figure 5 Experimental set-up for on-line aerosol fluorescence detection of particle-bound PAHs. (Reproduced from Niessner, by permission of Elsevier Science.)

The coupling of laser-induced RTP to fiber optic sensors may potentially be useful for field applications where fast determination of PAHs is needed. Limits of detection at the order of picograms were obtained for several PAHs, using a SSRTP fiber-optic sensor. Figure 6 shows typical emission spectra obtained by a laser-induced RTP sensor.

Figure 6 Laser induced RTP emission spectrum of a \(10^{-6}\) M pyrene solution obtained with a fiber-optic sensor. Phosphorescence emission was enhanced by 0.1 M TIOAc. Excitation wavelength was 337 nm. (Reproduced from Campiglia et al., by permission of the American Chemical Society.)

3.2.5 Infrared Spectrometry

Conventional dispersive infrared (IR) spectrometry is not a preferred method for PAH analysis. The disadvantages of this technique for PAH analysis are the lack of unique and significant structures that exhibit IR spectra, the relatively weak bands, and the fact that the IR band strength is not proportional to the concentration of the analyte. Moreover, as far as environmental samples are concerned, they usually contain numerous PAHs which all exhibit the typical C–H stretching in the region 3200–3000 cm\(^{-1}\) and the out of plane bending vibrations at 900–675 cm\(^{-1}\). Other IR absorption bands may be contributed by heteroatoms in the ring structure or by substituent groups on the ring. Thus, overlapping of spectral features due to various PAH compounds in a sample is very likely.

The development of FTIR spectroscopy along with the application of matrix isolation (MI) techniques has made IR spectroscopy more useful for PAH analysis. In particular, FTIR can follow the different stages of chromatographic separation and provide successful detection of PAH compounds.

In the MI procedure the compounds of interest are isolated in a rare-gas, IR transparent, matrix at low temperature (~10 K). Since interactions between the studied compound and the matrix are very weak, the molecules are trapped in a quasi-gas-phase environment. Rotations of the PAH molecules are reduced at the
low temperature, and the IR bands are narrowed, thus reducing the possibility of overlapping.\(^{(101)}\)

The positions of the absorption bands of matrix-isolated PAH molecules typically undergo only small shifts in the 0–15 cm\(^{-1}\) range, relative to their gas-phase values.\(^{(102,103)}\) IR band positions of matrix-isolated PAHs were reported for a large number of PAHs.\(^{(104)}\)

Several successful applications of MI FTIR spectroscopy in PAH analysis have been reported recently. Matrix-isolated techniques have been applied to measure the mid-IR spectra of several PAHs (naphthalene, anthracene, phenanthrene, 1,2-benzanthracene, chrysene, pyrene, tetracene, and triphenylene).\(^{(101)}\) The results showed a good agreement with theoretical calculations for the majority of IR-active vibrations of the examined PAHs. In addition, the analysis of 12 nitro-PAHs was accomplished recently.\(^{(104)}\)

The use of FTIR spectrometry to detect PAH compounds separated by GC analysis has been suggested and shown to provide complementary information to mass spectrometric data. Naturally, mass spectrometry cannot provide sufficient information for distinguishing between PAH isomers, whereas their IR spectra are significantly different. The GC/FTIR technique is carried out by passing the GC effluent through a gold-coated light pipe coupled to IR-transparent windows, while interferograms are continuously obtained. The interferograms of the various components undergo Fourier transformation, resulting in analysis of the PAH mixture.\(^{(105)}\)

Another GC/FTIR detection procedure is based on the MI technique, in which the effluent compound is trapped in a frozen matrix of an IR transparent gas on a rotating gold-plated disk. Interferograms are obtained after the GC run is completed. The detection limit for this method for one compound, pyrene, was 710 ng.\(^{(106)}\)

It is generally concluded that the applications of IR spectroscopy to PAH analysis provide complementary information that may not be obtained using other methods. Nevertheless, the IR-related techniques provide relatively poor sensitivity and selectivity in analysis of PAH compounds. Therefore, these techniques are recommended when the unique IR information (e.g., separation of isomers) is required.

### 3.2.6 Raman Spectroscopy

Raman spectroscopy is the measurement of the frequencies and the intensity of the light inelastically scattered from a molecule. The range of frequencies shifted from the incident light (Stokes and anti-Stokes lines) comprises the Raman spectrum of a molecule. The Raman shifts correspond to vibrational transitions in the scattering molecule.

Even though Raman scattering frequencies provide information about the vibrational transitions of the analyte molecule, as the IR absorption dose, the information obtained by these two methods is not identical. Frequencies permitted in the IR may be forbidden in Raman, and vice versa.

Most commonly, the Raman excitation is performed using a UV/VIS light source, hence the Raman bands are also observed around this region. Detection in this spectral range is easy, because many detecting devices are available, e.g. photomultiplier tubes, diode arrays, and CCDs. The ideal light source for Raman spectroscopy is a laser.\(^{(107)}\) The most frequently used lasers in Raman spectroscopy are the Ar or Kr-ion types. Sometimes these lasers pump CW dye lasers, providing tunable radiation. High repetition rate excimer laser-pumped pulsed-dye lasers are also applied. When a UV/VIS excitation source is used for PAH analysis, a broad fluorescence band is also expected. The fluorescence interferes with the Raman scattering; thus, the former has to be subtracted from the spectra, if possible. This fluorescence interference can be avoided in the analysis of most PAHs when an NIR laser is applied for excitation (e.g. CW neodymium:yttrium aluminum garnet (Nd:YAG) laser, irradiating at 1064 nm). The main drawbacks of using this spectral range are the loss of sensitivity due to the \(k^{-4}\) dependence of the scattering event and the decreasing quantum efficiency of the CCD detectors.\(^{(108)}\)

The major disadvantage of Raman spectroscopy is its low quantum yield: only 1 out of \(10^7\) photons of the incident light exhibits the Raman effect. This results in very weak signals. Therefore, spectral analysis based on Raman scattering requires high light throughput spectrophotometers, such as the Fourier transform type. Raman spectra free of fluorescence interference are commonly obtained by a FTIR system, which combines a Fourier transform interferometer and a Nd:YAG laser.\(^{(109)}\) Near-IR Fourier transform Raman spectra of several PAHs have been measured. These spectra exhibited distinct features, which enabled identification and analysis of multicomponent mixtures of PAHs.\(^{(110)}\)

Resonance excitation may raise the scattering power of PAHs by several orders of magnitude, allowing detection of low PAH levels. The resonance Raman intensities strongly depend on the excitation wavelength. Thus, by using a tuneable laser source one can selectively excite individual PAH compounds in a mixture. Resonance Raman spectroscopy using pulsed UV lasers is considered the most selective application of Raman spectroscopy in PAH analysis.\(^{(107)}\) Naphthalene, anthracene, phenanthrene, pyrene, and various substituted derivatives were examined by pulsed UV laser and exhibited resonance Raman bands.\(^{(111)}\) The UV resonance Raman enhancement enabled trace analysis of these species down to the ppb level.
This technique has also been applied as a detection system for HPLC. A mixture of five PAHs (naphthalene, fluorene, anthracene, pyrene, and chrysene), each compound at a concentration of $10^{-3}$ M, was separated by HPLC. The UV resonance Raman spectra ($\lambda_{ex} 230$ nm) of each compound supplied enough information for their identification.

Recently, the Raman technique has been applied to remote environmental sensing. Dielectric stack interference filters were incorporated within an UV optical fiber Raman probe head. This set-up enabled the removal of background silica Raman signals and Rayleigh scattering. Using a 244 nm UV optical fiber probe, resonance Raman spectra from 2 ppm (Figure 7a), 200 ppb (Figure 7b), and 20 ppb (Figure 7c) of pyrene in water were collected. The 1632 cm$^{-1}$ pyrene band is clearly observed in all spectra. In addition, equimolar aqueous solutions of pyrene and a visible fluorophore (R6G) were recorded (Figure 7d). This spectrum demonstrates the selectivity and sensitivity of this method. The R6G bands (Figure 7e) are not seen in the Raman spectra of pyrene and R6G. This technique was applied for in situ, on line monitoring of low PAH concentrations.

Since Raman spectroscopy is based on scattering of light, non-transparent samples can be examined. This is an advantage over other spectroscopic methods, which fail in analysis of solid environmental samples.

### 3.3 Photoelectric Aerosol Sensor

A sensor is usually a device that transduces a physical or chemical parameter into an electrical or optical device. Sensing techniques are expected to provide both high sensitivity and in situ, real-time information. Photoelectric aerosol sensing was studied using artificially PAH-coated carbon and sodium chloride aerosols. Aerosols were irradiated at 185 nm and photoelectric signals were measured. The signals obtained were linearly correlated to the amounts of each single PAH bound to the particle. It was found that the total photoelectric signal of internally mixed aerosols is described as a simple addition of the individual contributions of the adsorbed PAHs. The photoelectric aerosol sensor (PAS) was also applied to detection of particle-bound PAHs in diesel exhaust. In this case, the sensing system included a dilution unit and a measuring device. The system allowed dilution of exhaust aerosols in clean air at ratios of up to 1:32. Within the measuring device the neutral aerosols were separated from the charged particles and then introduced into the illumination section, where PAH mass-related particle photocharging took place. (The irradiation wavelength was 185 nm.) Under these conditions, only surface-enriched molecules possessing an extended π-electron system (e.g. PAH molecules) exhibit high photoelectric quantum yield. The PAS
provided a continuous sensitivity (\(<\text{ng m}^{-3}\)) of four and more ring-membered PAHs, but the photoelectric signal represented the sum of individual signals of all adsorbed PAHs.

### 3.4 Mass Spectrometry

Mass spectrometry is a well-established method for PAH analysis. Various techniques for ion generation, separation, and detection are used in MSs. In general, MSs rely on differences in the mass-to-charge ratio (\(m/z\)) of ionized PAH molecules for separation, identification, and quantification. The basic operating procedures of analytical mass spectrometry include: creating gas phase ions, separating the ions in space or time according to their \((m/z)\) ratio, and finally identification and quantification. Numerous mass spectrometric analytical methods are known, but this review will focus on two recent techniques, which are of special relevance to environmental detection of PAH compounds: laser desorption/laser ionization (two-step laser) time-of-flight (L2TOF) mass spectrometry and multiphoton ionization (MPI) time-of-flight mass spectrometry.

#### 3.4.1 Laser Desorption/Laser Ionization Time-of-flight Mass Spectrometry

L2TOF mass spectrometry is used for direct analysis of PAH compounds. In the first step an IR laser pulse desorbs the analyte molecules from the sample surface, or ablates neutral molecules from a solid sample or from a polymer membrane containing the analyte. No fragmentation or ionization occurs at that step. In the second step, a pulse from a tunable ultraviolet laser is used for resonance-enhanced two-photon ionization of the desorbed material. This procedure results in the formation of molecular ions. This mechanism is suitable for PAH molecules which are known to absorb the UV photons efficiently. Nonresonant two-photon ionization may also occur under these conditions, but with several orders of magnitude lower probability. Fragmentation is avoided by tuning the laser intensity and thus preventing absorption of another photon. Finally, ions are extracted by an electrical field and separated by their \(m/z\) ratio using time-of-flight mass spectrometry.

A laser desorption/laser ionization mass spectrum of a PVC membrane with eight PAH compounds, is shown in Figure 8. Only the intact parent ions are produced and detected.

The L2TOF mass spectra of 17 PAH compounds were recorded, when excitation was performed in the range 238–310 nm. It was proven that efficient ionization depends upon the existence of an intense absorption band. In addition, a long lifetime of the \(S_1\) state is essential for efficient resonance enhanced photoionization.

Environmental samples contain numerous PAHs. Among them are volatile PAH compounds, with vapor pressures between 10 Pa for naphthalene, to \(7 \times 10^{-4}\) Pa for pyrene. Mass spectrometry of solid environmental samples suffers from losses of the volatile material, e.g. volatile PAHs, due to the high vacuum conditions required. A possible solution to this problem is lowering the temperature of the sample, thus reducing the analyte’s vapor pressure. Another approach is forming a non-volatile PAH complex which dissociates during desorption or ionization. Complexation of PAHs with CDs, which has been mentioned in section 2.1, is also a useful technique for this purpose. The formation of solid-phase CT complexes of PAH–picric acid may also reduce PAH vapor pressure and thus reduce the loss of volatile PAHs such as anthracene during L2TOF/MS.

The spatial resolution capability of the laser desorption, combined with the high sensitivity of L2TOF/MS, enables the detection of microscopic PAH samples. Spatially resolved L2TOF/MS was applied to the detection and analysis of PAHs in atmospheric particles. Recent studies demonstrated that single-shot analysis of PAHs could be performed with micrometer-sized samples. PAHs in a single micrometer-sized diesel particle (from NIST SRM sample of diesel particulate matter, SRM 1640) were detected by L2TOF/MS. The limit of detection was estimated as lower than \(20\mu\text{g g}^{-1}\) diesel soot. In addition, other PAHs, which were not certified by NIST, were also detected.

Two-step laser time-of-flight mass spectrometry is a selective and sensitive technique, which utilizes soft ionization conditions for providing parent-dominated ion spectra. This method requires very little sample preparation. Furthermore, measurements can be performed...
within a few minutes. In addition, spatial resolution can be obtained by using a focused laser beam for desorption (resolution of 1–2 μm).\textsuperscript{130} These characteristics make L2TOF/MS an efficient technique for analyzing complex environmental samples. However, this method suffers of two main problems: it cannot distinguish between isomers, and quantification is difficult.\textsuperscript{118} Although the second problem has been addressed recently,\textsuperscript{131} the difficulty still remains, especially for complex environmental samples.

### 3.4.2 Multiphoton Ionization Time-of-flight Mass Spectrometry

When a molecule interacts with electromagnetic radiation it can absorb energy and become ionized if the photon energy is larger than its ionization energy. However, under certain conditions, a molecule can also be ionized when the photon energy is lower than its ionization energy. This nonlinear process is called multiphoton ionization/time-of-flight mass spectrometry (MPI/TOFMS) and it involves simultaneous absorption of several photons. The mechanism of MPI requires intensive radiation (\(\sim 10^{30}\) photons cm\(^{-2}\) s\(^{-1}\)) and short pulses, such as those readily obtained by lasers.

There are two classes of MPI processes: nonresonant MPI and resonance-enhanced multiphoton ionization (REMPI). The former process can be described as absorption of \(n\) photons through short-lived (\(\sim 10^{-15}\) s) virtual states (Figure 9a).

In REMPI the energy of \(m\) photons \((m < n)\) approaches the energy of a real intermediate state (Figure 9b). If the \(m\)-photon transition is allowed, the cross-section for \(n\)-photon ionization increases significantly.\textsuperscript{132}

In the case of naphthalene, for example, the first excited singlet state lies at an energy of 4.15 eV relative to the ground state. This energy gap corresponds to a wavelength of 299 nm. A laser that operates at this wavelength can reach the first PAH excited state with one photon. Another photon of this energy will ionize the molecule because naphthalene’s first ionization potential is 8.12 eV. In general, PAHs are particularly suitable for MPI because their absorption of light in the region 250–350 nm is very efficient.\textsuperscript{133}

Techniques based on MPI can be roughly divided into two main categories: MPI conductivity measurements, in which the photocurrent (electrons emitted in the MPI process) is detected; and MPI/MS measurements, in which the mass of the molecular ions is detected. The former will be discussed in section 4.1. The most common technique that detects the mass of ions produced by MPI processes is the MPI/TOFMS.

MPI/TOFMS is based on the differences in flight-time of equally accelerated PAH ions. Following the MPI step, an electric field accelerates all ions into a field-free drift region, where they obtain a kinetic energy of \(qV\) (\(q\) is the ion charge and \(V\) is the applied voltage). Since the kinetic energy of the ion is \(0.5 m v^2\), lighter ions reach higher velocities and therefore reach the detector after a shorter period of time.\textsuperscript{131}

Several applications of MPI or REMPI\textsuperscript{134} in MS of airborne particulate matter have been reported.\textsuperscript{135–139} On-line flame-sampling resonance-enhanced multiphoton ionization time-of-flight mass spectrometry (REMPI/TOFMS) has been performed in order to determine the concentrations of naphthalene, fluorene, and anthracene in a pure methane + oxygen–argon (1:5) diffusion flame.\textsuperscript{138} Detection limits as low as ppb were reported using a one-color (301.6 nm) or two-color (361.1 nm, excitation beam and 308 nm, ionization beam) REMPI on jet-cooled samples extracted from the flame. Figure 10 shows a REMPI/TOFMS mass spectrum of a jet-cooled sample from a heavily sooting flame.\textsuperscript{138}

Recently, a mobile laser MS (REMPI/TOFMS) was applied to on-line measurements of PAHs in a waste incineration pilot plant.\textsuperscript{140} The mobile device was adapted to harsh conditions of heat, dust and vibrations. PAHs were ionized selectively from the gas matrix by using UV laser irradiation (Nd: YAG at 266 nm or excimer KrF at 248 nm). Detection limits of naphthalene, for instance, were in the order of 10 ppt. Unfortunately, despite relatively high material selectivity and spectral resolution offered by various MS techniques, they are limited, at times, by the quite severe

---

vacuum conditions needed for most of the accurate time-of-flight measurement schemes.

3.5 Immunological Methods for the Detection and Quantification of Polycyclic Aromatic Hydrocarbons

Immunological methods are based on the high affinity reaction of an antibody–antigen complex. These types of reactions, which are characterized by specificity and extremely high sensitivity (femtomole levels) are used for PAH analysis. The two major immunoassays are radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA).

Antibodies (immunoglobulins) are proteins produced by an animal in response to the presence of a foreign substance, called an antigen. Low molecular weight organic compounds (MW < 5000), such as PAHs, are not immunogenic by themselves. These compounds, called haptens, must be coupled to a carrier protein (e.g. BSA, bovine serum albumin) in order to induce an immunogenic response. Either polyclonal or monoclonal antibodies can be produced. Polyclonal antibodies are produced by immunizing an animal and collecting its serum, which contains the antibodies. These antibodies are called polyclonal because they are produced by many different antibody-producing cells, and therefore they differ to some extent in their affinity for the antigen. In contrast to polyclonal antibodies, monoclonal antibodies are identical because they are produced by a population of identical cells (a clone). Each of these cells is descended from a single hybridoma cell formed by fusing an antibody-producing cell with a tumor cell, which is characterized by its capacity for unlimited proliferation.

Almost all antibody–antigen or antibody–hapten reactions can be modified for use as competition assays. Such modifications have been developed for measuring cross-reactivity among different haptens or antigens for the same antibody preparation, or quantitatively measuring the concentration of the same hapten or antigen in unknown samples.

The similar shapes, hydrophobicity, lack of hydrogen-bonding atoms, and other characteristics of PAHs contribute to the difficulties in the preparation of antibodies, which are highly selective for individual PAH compounds. Therefore, cross-reactivity is expected, especially when analyzing environmental samples. Selectivity can be improved by separating the compounds (e.g. by chromatography) prior to quantification by immunoassay.

3.5.1 Radioimmunoassay

In RIA the antigen or hapten is radiolabeled and serves as a tracer, while the nonradiolabeled antigen or hapten serves as an inhibitor. RIA involves competition between labeled and unlabeled antigen (or hapten) for binding to antibodies. The basic principle of RIA is that the likelihood of a molecule, labeled or unlabeled antigen, of binding the antibody is proportional to its concentration in the original mixture. Therefore, an isotope-dilution standard curve can be constructed. This is carried out by addition of ever-increasing known amounts of unlabeled antigen (inhibitor), while the concentration of labeled antigen (tracer) is kept constant. Then, the bound and free antigens (or haptens need to be separated). Separation can be accomplished by precipitating the antibody–antigen complex (e.g. by applying a second antibody). Finally, concentrations are determined from the radioactivity readings. After construction of the standard curves, an unknown antigen can be quantified by measuring the inhibition of the tracer binding.

Although RIA is not a common analytical technique, several applications to the analysis of biological PAHs have been proposed during the last few years.

3.5.2 Enzyme-linked Immunosorbent Assay

The ELISA is the most commonly used immunoassay technique for identification and quantification of PAHs. Figure 11 illustrates the general steps of the ELISA procedure.

In the first step the hapten (PAH molecule)–carrier protein conjugates are adsorbed onto the surface of the reaction vessel (a 96-microwell plate). A solution of the examined antibodies and antigen standards (or
Figure 11 Competitive ELISA: (1) Conjugates of PAH molecule-carrier protein are adsorbed onto the well; (2) wash; (3) incubation with specific antibodies in the presence (a) or absence (b) of standard or sample conjugates of PAH molecule–carrier protein; (4) wash; (5) incubation with anti-immunoglobulin enzyme; (6) wash; (7) incubation with enzyme substrate and measurement of product.

hapten–protein complexes) is then added. The binding of the antibodies to the immobilized hapten is competitively reduced due to the antigen addition. Wells are thoroughly washed so that only antibodies bound to immobilized hapten remain in the vessel. A second reagent is then added. This reagent is a conjugate of anti-immunoglobulin (an antibody originally produced from another animal, which binds the constant region of all antibodies) and an enzyme. Finally, after washing again, a colorless substrate is added and color develops as the enzymatic reaction progresses. The enzymatic product concentration is inversely proportional to the concentration of the added standard antigen. Quantification is performed by spectrophotometric measurements of the color intensity.

ELISA methods are generally much more sensitive than RIA, and therefore more popular for PAH analysis. However, as previously mentioned, the production of antibodies, which are highly selective for a specific PAH compound, is difficult. This is due to the similar characteristics of most PAH compounds. Cross-reactivity is expected, especially when environmental samples are considered.

ELISA techniques have also been applied to PAH analysis in air particulate matter, which has been analyzed by using a specific enzyme immunoassay for [benzo[\textit{a}]pyrene].\textsuperscript{149,150} In this case, however, the results were not compared with a conventional method. Recently, ELISA was applied to the analysis of 1-nitropyrene on diesel exhaust particles.\textsuperscript{150,151} This compound is one of the numerous products of incomplete combustion. It was chosen as a target analyte because of its high mutagenic and carcinogenic properties and because of its common appearance mainly on exhaust particles, emitted from diesel engines. It was shown that the detection of 1-nitropyrene, using the ELISA method, was applicable for the analysis of a large number of samples, in a short time. However, there were always substances present in the atmospheric samples, which could lead to overestimation of the target analyte due to their cross-activity in the ELISA.\textsuperscript{151} Direct application of the ELISA method resulted in a 6-fold overestimation. However, after a sample clean up, results were lowered to ~1.6-fold overestimation, which was attributed to the cross-reaction of 2-nitropyrene and 2-nitrofluoranthene.\textsuperscript{150} Therefore, it is concluded that absolute quantification of a single compound by the ELISA method is limited. Quite often, other substances present in the sample can cause an over-estimation of the target analyte due to their ELISA cross-reactivity.\textsuperscript{150,151}

A new approach of hapten screening was recently presented. The purpose of this research was to step towards developing sensitive ELISA for multianalyte PAH samples. Several new PAH haptens were applied for a systematic study of cross-reactivity with monoclonal antibodies. PAH haptens with different lengths of carboxylic acid chains, placed at various positions, were synthesized, and coupled with proteins. Several PAHs were used, e.g. naphthalene, fluorene, anthracene, pyrene, benzo[\textit{a}]pyrene. The goal was to maximize the difference in PAH cross-reactivity in the ELISA technique. As a result, the benzo[\textit{a}]pyrene detection limit
obtained by ELISA was ca. 150-fold lower than that obtained by GC.\textsuperscript{\textsuperscript{145}}

Compact kits for on-site PAH detection and screening, applying the ELISA technology, were developed and are now commercially available.\textsuperscript{\textsuperscript{152,153}} Such a test kit for screening PAHs in soils has been validated by the USEPA (method number 4035).\textsuperscript{\textsuperscript{154}}

3.5.3 Immunopurification Extraction and Chromatography

Selective isolation, extraction and clean-up of PAHs from complex environmental samples (soil, water and waste) can be accomplished using antigen–antibody interactions.\textsuperscript{\textsuperscript{155–157}} These methods are based on extraction of PAHs from samples onto an immunosorbent. The benefits of immunosorbent extraction techniques are the simplicity, the reduced amount of hazardous organic solvents and the relatively low cost.

Coupling of immunosorbent SPE with liquid chromatography analysis was successful in the determination and quantification of PAHs in environmental samples, down to the ppb level.\textsuperscript{\textsuperscript{155,156}} The unavoidable cross-reactivity of specific antibodies (anti-pyrene for instance) with a number of PAHs, can be advantageous for extraction and clean-up applications. Thus, antibodies that possess an extended cross-reactivity are required for preparation of class-specific immunosorbents.

Immunopurification chromatography (IAC) utilizes the interactions between an immobilized antibody and the analyte (antigen or hapten) in order to selectively extract the analyte from a complex sample matrix (e.g. environmental samples).\textsuperscript{\textsuperscript{158,159}} Immunopurification columns are packed with support material, e.g. silica, which contains immobilized antibodies. The latter are either covalently bonded or physically adsorbed to the support material.

Unfortunately, both of these immobilization techniques suffer from some disadvantages: the physical adsorption of antibodies may result in unstable columns, while the covalent binding may impose changes in antibody conformation. A partial solution for these problems has been suggested. It is based on physical trapping of the antibodies in the pores of a silicate glass prepared by sol–gel techniques.\textsuperscript{\textsuperscript{158,159}} The mild conditions under which the column is prepared do not destroy the molecular recognition.

Several PAH antibodies have been applied in IAC. In particular, anti-pyrene\textsuperscript{\textsuperscript{159}} and anti-1-nitro-pyrene\textsuperscript{\textsuperscript{158}} have been studied in detail. It is commonly concluded that the main drawback of the IAC technique is that the selectivity of these type of columns is limited due to the cross-reactivity of the antibodies with other PAH compounds.

4 RECENT ADVANCES IN THE ANALYSIS OF ENVIRONMENTALLY OCCURRING POLYCYCLIC AROMATIC HYDROCARBONS

In this section several new analytical techniques which have considerable potential in future environmental PAH analysis are discussed. The feasibility of these techniques has already been demonstrated, but, they are not yet available commercially. Further research and development is required for final validation and general acceptance of these methods.

4.1 Laser-induced Multiphoton Ionization/Fast Conductivity

The principle of laser-induced MPI has been described in section 3.4.2. It was mentioned that MPI-based techniques are roughly divided into two main categories: MPI/MS (previously described) and MPI conductivity measurements, in which the photocurrent (electrons emitted in the MPI process) is detected. The latter is described in this section.

A photoionization spectrum, namely the photocurrent vs the laser excitation wavelength, $\lambda_{\text{exc}}$, can be obtained using the conductivity MPI technique. These spectra possess peaks in the vicinity of the resonant wavelengths. In resonant MPI conductivity measurements, changing $\lambda_{\text{exc}}$ results in photocurrent signals that correspond to excitation of intermediate resonance. The MPI spectrum is, therefore, a fingerprint of the analyte molecule.\textsuperscript{\textsuperscript{132}}

A block diagram of a typical multiphoton ionization fast-conductivity (MPI/FC) facility is shown in Figure 12. Laser two-photon MPI conductivity measurement is a selective and sensitive method for the detection of photoabsorbing molecules such as various PAH compounds. This technique has been applied in both polar

![Figure 12](image-url)
and nonpolar solvents\textsuperscript{(160–163)} on metal surfaces,\textsuperscript{(164,165)} on a water surface,\textsuperscript{(166–171)} and on an interface region in a two-phase system.\textsuperscript{(172)}

MPI conductivity measurements are of considerable environmental value, due to their potential for operating under ambient conditions. Therefore, this technique allows for in situ, on line measurements of PAHs in environmental samples without pretreatment and extraction procedures. Quite obviously, measurements of MPI photocurrents require the substrate to be conductive. However, most environmental matrices are insulators. Therefore, for many years it was believed that this technique could not be applied to environmental PAH analysis. A recent study showed that MPI measurement, under certain conditions, can be performed on insulators, provided that a certain humidity is present. The effects due to humidity were quantified and it was found that the natural humidity of environmental samples, due to their exposure to ambient air, is adequate for allowing MPI analysis. For example, natural soil moisture is sufficient for trace analysis of organic contamination, e.g. PAHs, by fast-conductance MPI.\textsuperscript{(173,174)} Clearly, this finding opened up the possibility of applying similar experimental schemes to any porous substrate of interest, e.g. glass/paper filters, plant leaves (open field vegetation), and certain food products. Preliminary field tests were also conducted and reported. In these applications the data acquisition facilities were of a reasonably low cost, as well as being user-friendly and simple to operate.\textsuperscript{(175)}

Recently, the MPI/FC technique has been applied to the detection of PAH-polluted aerosols, i.e. motor car exhaust emissions and cigarette smoke. Aerosols were sampled on line by means of renewable water microdroplets. As shown in Figure 13, on-line PAH analysis is feasible. Detection limits as low as 1 pg were obtained for pyrene-contaminated renewable microdroplets.\textsuperscript{(176)}

Clearly, the liquid droplet technique offers an easily engineered renewable sampling of gaseous PAH pollutants and PAH contaminated aerosols. Some poorly dissolving airborne PAH compounds could readily reach the aqueous solubility limit and precipitate on the surface of the sampling water microdroplet. However, the same MPI/FC technique can be applied for measuring low aqueous solubility of PAHs and characterization of their adsorption, without any sample preparation.\textsuperscript{(176)}

4.2 Multiphoton Ionization–Time-resolved Ion-induced Charges

A new, simple, detection system, based on time resolution of ion-induced charges in MPI of PAH compounds in air has been suggested.\textsuperscript{(177,178)} The system is suitable for on-line air monitoring and has been tested for the detection of simple PAH molecules.

![Figure 13](image-url)  
**Figure 13** Photoionization current, $I = I(t)$, obtained by the MPI/FC technique, applied to a renewable water droplet. The droplet was contaminated with motor exhaust gases and cigarette smoke. Note that the area under the respective $I(t)$ curves corresponds to the detected photocharge, $Q$, which, in turn, is proportional to the amount of photoabsorbing organic traces. Excitation was carried out by a pulsed nitrogen laser at 337.1 nm. (Reproduced from Gridin et al.,\textsuperscript{(17)} by permission of the American Chemical Society.)

Two-photon quasi-resonant ionization is carried out by a few mW cm$^{-2}$ of a KrF excimer laser radiation at 248 nm. Under these conditions, none of the regular atmospheric gas is ionized. The quasi-resonant ionization of PAHs at 248 nm provides the required selectivity.

This technique provides a certain level of mass analysis, using the following set-up. The examined air is introduced into a long cylindrical chamber, and its pressure is reduced until the mean free path reaches an order of 1 cm. A parallel laser beam passes into this chamber, resulting in MPI of the PAHs. Two long electrodes are placed parallel to the laser beam. The MPI charges are separated and slightly accelerated towards the electrodes. Quantification of the PAHs is based on the number of charges, while mass detection is based on the time-resolved electrode voltage change during the ions’ flight. The latter is a result of the mirror-charges induced by the PAH ions, and it was shown that their temporal profile is a clear function of the masses. This new detection system is characterized by its simplicity, large ionization volume, and high ion collection efficiency.

A set of computer algorithms was required in order to analyze the data and to ascertain the ionic mass. Detection limits in the order of ng m$^{-3}$ in the detection chamber were reported, which corresponds to ambient air concentrations in the sub-ppm range.

4.3 Imaging Methods

Chemical imaging, which combines spectral and spatial resolution, is a relatively new technique in analytical
chemistry. This promising technology, which is still under investigation, may be applied successfully to environmental analysis of PAH compounds.

Several imaging methods have been investigated recently. Most of these methods applied imaging Raman analysis, but fluorescence imaging has been developed as well. Old-type fluorescence imaging techniques were based on irradiation of the sample with UV light, and observation of the imaging fluorescence through optical filters. This method provided very limited spectral information, which was not sufficient for the identification of compounds or the resolution of mixtures.

The above problem, as well as optical throughput problems, were recently solved by Fourier transform imaging spectrometry. Both spatial and spectral resolution were obtained when a Fourier transform spectrometer was coupled to a microscope and a CCD camera. This imaging device provides a full fluorescence spectrum at each pixel. The imaging fluorescence provides both chemical and morphological information, which is useful in environmental analysis.

The imaging fluorescence technique has been applied to PAH particulate materials. The experimental set-up consisted of a fluorescence microscope, a Fourier transform imaging spectrometer and a CCD camera, as shown schematically in Figure 14. This set-up was applied to the analysis of PAH aerosols on glass fiber filters.

Inspection of PAH contaminated filters through a fluorescence microscope provides 3-D maps, as shown in Figure 15(a). In this example, a glass filter contaminated with a mixture of PAH aerosols was inspected (the image area was 213 × 232 µm). Here, the wavelength-integrated image is shown. The peaks represent the emitting contaminating aerosols, while the contour map at the bottom indicates their precise location and size. This figure presents the integrated intensities, but the imaging Fourier transform spectrometer provides a full spectrum at each pixel. Therefore, a proper classification can be carried out, resolving the chemical identity of each peak. The spectral classification procedure results in a 2-D mapping of the filter contamination (Figure 15b). This figure corresponds to the same filter area as Figure 15(a). The dark and light gray pixels represent contamination by perylene and coronene respectively.

In addition to the combined chemical and morphological information, this technique provides excellent sensitivity. The absolute detection limits (for aerosols collected on a glass fiber filter) were estimated to be as low as 0.25 pg, corresponding to an air concentration of 0.5 pg m⁻³, when integrated in 1 min. These results correspond to almost on-line particulate PAH analysis.

The above fluorescence imaging technique was also applied to the analysis of PAHs compounds sorbed on sand particles. The absolute sensitivity in this case was in the pg range, which corresponds to global sand contamination in the ppm range.

A somewhat different imaging technique, based on an acousto-optic tuneable filter (ATOF) combined with a CCD detector, was also reported. The ATOF is a solid-state electronic device, which replaces the grating of a traditional spectrometer. Its principle of operation...
5 CONCLUDING REMARKS

Although numerous analytical techniques are available, environmental PAH analysis is still considered a challenging task. Simple PAH mixtures in homogeneous matrixes can now be handled by a variety of methods, but analysis of a complicated environmental sample requires time-consuming investigation of the particular case in hand. Consequently, not all qualified analytical laboratories are capable of handling complicated PAH analysis. In most cases, this is a task for specialists. Nevertheless, several emerging technologies are now under investigation in many laboratories (some of them were briefly mentioned here). A promising direction is the development of PAH sensors, based on recent advances in material science (chemical sensors) and in optoelectronics (physical sensors). It is hoped that these methods will provide a better solution to the problem of on-line and in situ detection of PAHs in the environment.

is simple. When an acoustic wave propagates in an anisotropic crystal it produces a periodic modulation of the refractive index. The result is a grating that diffracts portions of an incident light beam. When the ATOF is placed in front of a CCD detector it enables both spectral and spatial resolution. The advantages of the ATOF device for imaging purposes are the lack of moving parts and the relatively rapid tuneability over a broad spectral range. An imaging spectrometer for solid-surface room-temperature phosphorimetry, based on ATOF, was recently reported as a tool for PAH analysis. Nevertheless, the major drawback of ATOF devices for PAH analysis is their relatively low optical throughput. This problem becomes crucial when PAH traces are concerned.

Particle-induced X-ray emission (PIXE) is an analytical method based upon X-ray spectrometry. In the vast majority of applications, a proton beam is used to eject inner-shell electrons from atoms in a solid specimen (target). When the resulting vacancies are filled by outer-shell electrons, characteristic X-rays whose energies identify the particular atom are emitted.

Proton PIXE is performed by a small particle accelerator (the most widely used is the Van de Graaff machine at a 2–3 MV voltage, more recently also small tandem accelerators), that provides a beam of protons. The beam emerging from the accelerator, stabilized and directed by electrostatic and magnetic steering elements in a high vacuum line, enters the specimen chamber through suitable collimators. The X-ray detection system, housed in the chamber, is generally a Si(Li) device, that combines the advantage of high efficiency in the X-ray energy region of interest (usually 2–20 keV) with a good energy resolution.

A typical PIXE spectrum consists of characteristic X-ray peaks superimposed on a background due to bremsstrahlung radiations and nuclear reactions induced by the beam. The area of each peak is related directly to the concentration of the corresponding element in the specimen. Various software codes have been developed to deconvolute spectra and to accurately calculate peak areas.

PIXE intrinsic detection limit (DL) is not very much below 1 ppm (mg kg$^{-1}$) in a given matrix. It offers its maximum sensitivity in two atomic number ($Z$) regions: $20 < Z < 35$ and $75 < Z < 85$. Measurement errors are in the order of 10%, depending mainly on the target preparation procedure and on the slight variability of the proton flux.

The PIXE technique allows fast (few minutes), non-destructive, highly sensitive simultaneous determinations of a wide group of elements ($12 \leq Z \leq 85$), without large variations in sensitivity among different elements. The total element concentration is measured by PIXE, independent of different oxidation states. Adequate sample preparation procedures may be required in environmental PIXE applications since solid targets have to be exposed to the particle beam. Thin targets are preferable, in order to minimize matrix effects. For thin samples and for light-element matrices, PIXE has superior sensitivity compared to X-ray fluorescence (XRF). In heavy-element matrices XRF is preferable. DLs for inductively coupled plasma atomic emission spectroscopy (ICPAES) may be lower than for PIXE (depending on the sample dilution factor), but the topic of interferences is much more complex for ICPAES than for PIXE.
1 INTRODUCTION

Highly sensitive analytical techniques and adequate procedures are of primary importance in order to perform reliable concentration measurements of trace inorganics in the environment.

The study of environmental processes requires the examination of different media, such as air, water and sediment. Among the analytical techniques that employ accelerators in the study of the environment, PIXE has proven a useful tool for the study of trace element distribution in ecosystems, both in terms of pollution measurement monitoring as well as for geochemical and geophysical studies. The major features of this technique are multi-element analysis, high sensitivity and excellent DLs across a wide range of atomic numbers. An additional advantage is the speed of analysis for a wide variety of samples. Given its main capabilities, PIXE also provides a preliminary insight into the behavior of the elements in the samples while showing the relative abundances of the elements present.

However, it must be stressed that adequate sample-preparation procedures and suitable measurement conditions are required in order to make full use of PIXE capabilities. Since the concentrations of trace elements in the examined media range from parts per million (milligrams per kilogram) to fractions of a part per trillion (nanogram per kilogram), a preconcentration treatment is generally needed since the PIXE intrinsic DL is not very much below 1 ppm in a given matrix. In addition, PIXE requires solid specimens, so that liquid samples must undergo some pretreatment before exposure to the beam, and both liquid and aerosol samples must be deposited on suitable backings. The optimum sensitivity of PIXE is obtained in the analysis of trace elements in a matrix of light elements and with thin samples of low mass. It follows that some effort is needed to prepare targets with these features using different natural specimens.

Samples of any size and shape can be irradiated using the so-called external-beam technique, where the particle beam (protons in the vast majority of applications) is taken out in the ambient air through a thin window at the end of the vacuum line of the accelerator. Obviously the sensitivity is impaired by the air layer crossed by the beam, therefore this version of PIXE is not suitable for accurate environmental analysis. On the other hand, environmental studies can benefit from the development of another variation of proton PIXE, called proton microprobe, or microparticle-induced X-ray emission (μ-PIXE), that in principle is analogous to the electron microprobe or scanning electron microscope–energy dispersive X-ray analyzer (SEM/EDAX), where a proton accelerator replaces the electron gun. The proton beam can be scanned across the surface of the specimen, giving an elemental mapping of the tested area. The μ-PIXE DLs are better by a factor of about 100 than the electron microprobe DLs, and it is the real advantage of μ-PIXE compared to SEM/EDAX, that surely is the best technique to obtain images of the specimen at the micron-size scale.

2 THE PARTICLE-INDUCED X-RAY EMISSION TECHNIQUE PERFORMED BY PROTON BEAMS

2.1 X-ray Production by Means of Accelerated Protons

PIXE is based on spectrometry of the characteristic X-rays emitted by target atoms whose innermost orbitals have been ionized by accelerated particles (Coulomb interaction). When the resulting vacancies are filled by outer-shell electrons, characteristic X-rays whose energies identify the particular atom are emitted (mainly K and L X-rays, M in a smaller amount). The vacancy production for protons at the energy used may be calculated by means of different theoretical approximations [binary encounter approximation (BEA), semi classical approximation (SCA), plane wave Born approximation (PWBA)\(^1\) and energy loss during collision (coulomb (field deflection) perturbation (of atomic) stationary states (relativistic) effects (ECPSSR)\(^2\)] which all give similar results for the cross-sections of producing vacancies (i.e. shell or sub-shell ionization cross-sections). Significant K, L-shell ionization cross-sections for protons predicted by ECPSSR are shown in Figure 1. Analytical

![Figure 1](https://via.placeholder.com/150)

**Figure 1** Significant K, L-shell ionization cross-sections for protons (barns) predicted by ECPSSR as a function of proton energy. (Reproduced by permission of Wiley & Sons from S.A.E. Johansson, J.L. Campbell, *P.I.X.E. A Novel Technique for Elemental Analysis*, John Wiley & Sons, 1988.)
formulae for cross-section calculation based on experimental data and on measured K- and L-shell ionization cross-sections are available in the literature. These clearly show that ionization cross-sections increase with increasing proton energy and decreasing target atomic number (with slight variations between neighboring elements).

The probability of an X-ray emission when a vacancy is filled, instead of an Auger electron, is known as the fluorescence yield for the shell or subshell in question (Figure 2). The cross-section for emission of an X-ray is the product of the ionization cross-section and the fluorescence yield for a given shell or subshell. The filling of vacancies by means of transitions from outer shells, produces X-ray lines of different intensities (relative emission rates), theoretically calculated and experimentally measured by several authors. The K and L or L and M lines from the same element may be simultaneously present in a PIXE spectrum. The number of emitted X-ray photons for a given atomic transition is proportional to its production cross-section for protons at the particular energy, to the relative intensity of the transition and, obviously, to the flux of protons.

The PIXE spectrum resulting from an irradiated specimen (Figure 3) is the sum of different contributions:

- the characteristic X-ray peaks (mainly K lines for medium and L lines for heavy elements);
where $Z$ is the atomic number of the projectile. The particle bremsstrahlung is responsible for the high-energy background in a PIXE spectrum, and decreases with increased beam particle energy.\(^6\)

The SEB is the principal contribution to the low-energy continuum X-ray background in PIXE X-ray spectra. It results from the slowing down in the target of electrons ejected from atoms through inelastic collisions. The maximum kinetic energy $T_m$ that can be transferred to an electron in a head-on collision from a projectile to a free stationary electron of mass $m$ is given by Equation (2):

$$T_m = \left( \frac{4m}{M_p} \right) E_p$$

where $M_p$, $E_p$ are projectile mass and energy. It follows that SEB is a continuum spectrum which can be very intense below energy $T_m$, which falls off very rapidly above this photon energy.\(^6\) Given the dependence of $T_m$ on $E_p$, the SEB effect increases with rising particle energy.

SEB has an anisotropic distribution in angle; its maximum intensity is at (somewhat less than) 90° backward angle, while diminishing asymmetrically on both sides of this maximum.\(^7\) Depending on the slope of the curve, an angle of 135° is generally preferred for X-ray detector placement.

The intensity of the proton bremsstrahlung is much less than that induced by an electron beam, because PB is proportional to the square of the charged particle deceleration (i.e. the square of the Coulombic force for particle mass unit acting on the projectiles). Given the higher proton mass, the intensity of their bremsstrahlung is negligible in comparison with the electron one. Even if of low intensity, the proton bremsstrahlung cannot disappear, because the theoretical PB cross-section contains the term (Equation 1):

$$\left( \frac{Z_p}{A_p} - \frac{Z_t}{A_t} \right)^2$$

where $Z_{p,t}$ and $A_{p,t}$ are atomic number and atomic mass for projectiles and target. For low-atomic-number targets $Z_t/A_t$ is approximately 0.5: it follows that the PB should have zero intensity for heavy projectile ions, but not for protons. The particle bremsstrahlung is responsible for the high-energy background in a PIXE spectrum, and decreases with increased beam particle energy.\(^6\)

![Figure 4](image)

**Figure 4** Continuous background from PB and SEB for three different projectiles, 3 MeV each per nucleon, incident on a thin carbon target. Data for helium and oxygen are normalized by the inverse of the square of the projectile nuclear charge $Z$. (Reproduced by permission of Wiley & Sons from S.A.E. Johansson, J.L. Campbell, *PIXE: A Novel Technique for Elemental Analysis*, John Wiley & Sons, 1988.)

- the $\gamma$-rays from nuclear reactions, $\gamma$ background (GB) induced by the beam.

The intensity of the proton bremsstrahlung is much less than that induced by an electron beam, because PB is proportional to the square of the charged particle deceleration (i.e. the square of the Coulombic force for particle mass unit acting on the projectiles). Given the higher proton mass, the intensity of their bremsstrahlung is negligible in comparison with the electron one. Even if of low intensity, the proton bremsstrahlung cannot disappear, because the theoretical PB cross-section contains the term (Equation 1):

where $Z_{p,t}$ and $A_{p,t}$ are atomic number and atomic mass for projectiles and target. For low-atomic-number targets $Z_t/A_t$ is approximately 0.5: it follows that the PB should have zero intensity for heavy projectile ions, but not for protons. The particle bremsstrahlung is responsible for the high-energy background in a PIXE spectrum, and decreases with increased beam particle energy.\(^6\)

The SEB is the principal contribution to the low-energy continuum X-ray background in PIXE X-ray spectra. It results from the slowing down in the target of electrons ejected from atoms through inelastic collisions. The maximum kinetic energy $T_m$ that can be transferred in a head-on collision from a projectile to a free stationary electron of mass $m$ is given by Equation (2):

$$T_m = \left( \frac{4m}{M_p} \right) E_p$$

where $M_p$, $E_p$ are projectile mass and energy. It follows that SEB is a continuum spectrum which can be very intense below energy $T_m$, and which falls off very rapidly above this photon energy.\(^6\) Given the dependence of $T_m$ on $E_p$, the SEB effect increases with rising particle energy.

SEB has an anisotropic distribution in angle; its maximum intensity is at (somewhat less than) 90° backward angle, while diminishing asymmetrically on both sides of this maximum.\(^7\) Depending on the slope of the curve, an angle of 135° is generally preferred for X-ray detector placement.

2.2 Experimental Set-up

The great majority of accelerators employed for analysis are single-ended Van de Graaff machines, employing protons as projectiles for PIXE (in a few cases helium or heavier ions are also used), and which accelerate through a voltage of typically 2–3 MV.\(^8\) These accelerators may

---

**ENVIRONMENT: WATER AND WASTE**
provide currents up to tens of microamperes, but for PIXE the current is limited to tens of nanoamperes onto the target, also minimizing sample damage by heating and high detector dead times. There is also increased use of small machines, the tandem accelerators, that allow the use of half the voltage required by conventional accelerators to provide particles of the same energy, with considerable reduction in size and price.

The beam emerging from the accelerator is at first stabilized by passing through a slit into a deflector magnet, then driven axially in a beam line, evacuated typically to \(10^{-6}\) Torr, by means of electrostatic equipment and steering magnets, to the irradiation chamber. Before entering the chamber, the beam is diffused through a thin metal foil and then collimated in order to produce a spot on the specimens of well-defined size and with rectangular distribution of proton flux across the beam.

Various kinds of specimens may be analyzed by PIXE, both thin samples, for which the loss of particle beam energy passing the sample may be neglected, or thick samples, that completely stop the beam. Among the devices installed in the irradiation chamber, a Faraday cup is placed beyond the sample (with respect to the incident beam), which measures the transmitted particle current intensity, in order to evaluate the charge collected on the target. Obviously it is not possible to perform this measure for thick samples: in this case the current has to be monitored in other ways, either by intercepting the beam before it enters the chamber or by means of current integrators connected to the (conducting) specimen.

The X-rays emitted from the sample are detected (in most PIXE set-ups) by means of a high-resolution, high-efficiency Si(Li) detector. These detectors have an energy resolution of about 150 eV (at 5.9 keV), that permits resolution of the K lines of neighboring elements such as the transition metals. The Si(Li) efficiency varies with X-ray energy (it is close to 100% in the energy range 5 to 15 keV, and higher than 80% between 2 and 20 keV), because it is limited at low energies by X-ray absorption (in various windows and layers) and at high energies by penetration through the crystal; experimental efficiency determination is usually carried out using calibrated X-ray sources.

The resulting PIXE spectrum collected in a multichannel analyzer may be immediately passed to an on-line computer to be examined by suitable software codes.

The PIXE set-up used for environmental samples at the National Institute of Nuclear Physics (INFN) Laboratory of Legnaro (Padova, Italy) is shown in Figure 5. The incident particles are protons accelerated to 1.8 MeV by a Van de Graaff accelerator. To obtain a homogeneous circular beam spot at the target, the beam is diffused through a Ni foil, of thickness 450 \(\mu\)g cm\(^{-2}\), and subsequent carbon collimators pick off the central part of the beam, approximately 1.5 cm diameter. The Si(Li) detector (resolution: 150 eV at 5.9 KeV, solid angle between the target and the sensitive detector area: 0.0198 sr) is placed at 135° from the beam and in front of the target.

![Figure 5](image-url)

**Figure 5** The PIXE set-up for environmental analysis at INFN Laboratory of Legnaro (Padova, Italy): 1, Particle beam; 2, Ni diffuser; 3, quartz; 4, valve; 5, carbon collimator; 6, irradiation chamber; 7, carbon covering; 8, Faraday cup; 9, sample holder; 10, window; 11 Si(Li) detector and electronic devices.
of the target (the detector axis is normal to the target surface). Under these conditions X-ray attenuation in the target is limited. Mylar™ absorbers of various thickness or a “funny” filter (an absorber with a central hole) are placed in front of the detector.

Typically a 150–300 µm Mylar™ absorber is used in sea and fresh water samples analyses, in which major light elements may be exceptionally abundant, while so-called “funny” filters are preferable for aerosol specimens. The aerosol specimens yield X-ray intense peaks of low-Z elements superimposed on an intense low-energy background, that would both be strongly attenuated by Mylar™ absorbers. By piercing a central hole in the absorbing filter foil, a percentage of the X-rays within the detector’s solid angle (related to the hole area) is not attenuated. This “funny” filter balances the intensity between the low- and high-energy regions of the spectrum. The use of “critical” absorbers is generally not required in these analyses. For pore water and mainly for sediment samples in which the relative abundance of a measured element can be particularly high, an absorber that selectively attenuates (i.e. a critical absorber) the element’s most intense lines may be used. Such an absorber attenuates the X-rays that lie just above its absorption edge and transmits a greater fraction of the photons at higher (and at some lower) energies.

2.3 Measurements of Thin and Thick Targets

The energy loss of a proton beam and the X-ray attenuation are considered to be negligible in a so-called “infinitely thin” target. This definition obviously depends on the incident proton energies $E_p$, that is assumed constant within the target material, and on the nature and thickness of the exposed sample matrix, which would determine the extent, if any, of the proton energy degradation in the target. A thin environmental specimen is generally prepared by deposition of a small amount of material (such as powder, solid residue or precipitate from liquids, ultrathin slice, etc.), on a low-Z backing foil that should be as thin as possible. A conducting backing would be preferable, in order to avoid an improvement of the background by periodic discharging (to the nearest conductor) of the backing. On the other hand, the use of conducting (higher Z) backing improves PB intensity; in addition, the energies of the characteristic X-rays emitted from the backing material are sufficiently high to interfere with the peaks of the elements to be analyzed. For these reasons low-Z insulating material backings are generally used, and several solutions to their charging up are available: the specimen may be coated by a conducting carbon film, or sprayed with an electron current sufficient to maintain neutrality (the risk of these procedures is the introduction of spurious trace elements).

For example, for a proton beam of 2–4 MeV energy, and with thin carbon or polymer backings, a thin target is considered to be one with a thickness of the order of less than 1 mg cm$^{-2}$.

The number $N$ of characteristic X-ray photons emitted (i.e. the yield of X-rays) as a result of a transition occurring in a particular element, of atomic number $Z$ and atomic mass $A$, due to the passage of $N_p$ protons in a thin target is given by Equation (3):

$$N(Z) = N_p M(Z) \sigma_z(E_p) w Z_{\alpha} Z_{\beta} \left( \frac{\Omega}{4\pi} \right) \frac{t_z N_{av}}{A}$$  \hspace{1cm} (3)$$

where $\sigma_z(E_p)$ is the ionization cross-section of the given shell/subshell for proton energy $E_p$: $w z$ and $I_{\alpha}$, the fluorescence yield and the relative intensity for the particular transition; $I_{\beta}$, the absolute detector efficiency at the considered X-ray energy; $t_z$, the transmission factor through any absorber interposed between the target and the detector at the considered X-ray energy; $N_{av}$, Avogadro’s number; and $\Omega$, the fractional solid angle subtended by the detector. $M(Z)$ is the mass of a thin, uniform elemental film per unit beam area, in the case of a beam normal to the target surface. $M(Z)$ is given by the product of target areal density ($\rho_z$) and target thickness, t. Equation (3) allows absolute analysis: $M(Z)$ may be calculated if all the other terms were determined, with an accuracy of about 10%, for K shells, with more uncertainty for L shells. In spite of it, and even if a reliable data base and physical quantities are available, an experimental calibration by means of measurements of standard samples is frequently performed. It is the case for targets from environmental specimens that reference samples of similar matrices are more suitable for use to calibrate the set-up, as will be discussed in section 3.4.

The target may be thick enough to entirely stop the beam; the range of 2 MeV protons in a carbon foil is about 8 mg cm$^{-2}$, while the range is less than 20 mg cm$^{-2}$ for 3 MeV protons in organic material. This is the case for specimens that cannot be reduced to a thin sample; archaeological specimens or artefacts apart, among environmental samples the mineralogical ones, that should be kept in their original state, are generally thick enough to stop the beam. Other examples are pelletized samples, mainly biological or geological. In all these cases the beam proton energy, $E_p$, is reduced to zero within the target, and an integration of the ionization cross-sections and of the photon transmission from energy $E = E_p$ down to zero is needed. This variant of PIXE is sometimes referred to as thick target particle-induced X-ray emission (TTPIXE) (Thick Target PIXE). The X-ray yield from a given element ($Z$) uniformly distributed within a thick specimen is given...
by Equation (4):

\[ N(Z) = N_p C_z w_z Z_d E_z \left( \frac{\Omega}{4\pi} \frac{N_{av}}{A} \right) \int_{E_p}^{0} \frac{\sigma_z(E) T_z(E)}{S(E)} \, dE \]  

where \( C_z \) is the concentration of the element \( Z \) of interest. \( T_z(E) \) describes the transmission of X-rays in the thick specimen, and includes the mass absorption coefficient for photons of the \( Z \)th element in the specimen matrix, obtained by summing over the matrix constituents, which should be known. \( S(E) \) is the stopping power of the sample matrix, obtainable from a combination of the component stopping powers. For a more detailed description, see Johansson and Campbell\(^{(6)}\) and Johansson, Campbell and Malmqvist.\(^{(7)}\) The other quantities have been already defined.

The PIXE capability for trace and ultratrace measurements represents a great advantage in environmental analysis: this feature may be impaired when high-intensity peaks from very abundant elements and when considerable matrix background are present in the spectrum. Thick targets frequently fall in this category. Their background emission may be further improved by charging insulating specimen materials. It follows that, even if largely used, TTPXIE finds its more relevant application mainly in biology, geology or archaeology, as previously noticed, than in the environmental field.

Specimens may be prepared, following the thin target protocol, having thicknesses up to a few milligrams per square centimeter, involving an appreciable proton energy loss within the sample. The X-ray yield in these intermediate thickness targets may be obtained from the same approach used for thick samples, with the difference being that the proton energy integration limits becomes the entrance \( E_p \) energy and the final \( E_t \) energy of the proton beam, as it emerges from the target. A knowledge of the target thickness and of its matrix composition is required in order to evaluate the matrix mass absorption coefficient for characteristic X-rays and the stopping power in the specimen. A simple scheme for the matrix corrections for these intermediate thickness specimen, that has been proposed and developed,\(^{(10)}\) is presented in section 3.3. Simple correction factors allow one to relate the yield for intermediate thickness targets to thin target ones, without any previous knowledge of the composition of the specimen.

### 2.4 Intrinsic Sensitivity of the Technique

PIXE analytical sensitivities are approx. 1 ppm in the exposed target material. This means that the technique is able to detect trace elements at picogram level in a suitable matrix. Figure 6 presents sensitivity curves (i.e. the yield behaviors) measured on thin specimens by means of standard targets. The region of highest yield corresponds to the limit of detection (LOD) minima. Figure 7\(^{(11)}\) shows the limits of detection for a thin organic specimen on a thin backing foil (0.1 mg cm\(^{-2}\)) in terms of concentration, with the following experimental parameters:
detector resolution 165 eV, solid angle 0.003 × 4π, collected charge 10 µC. The highest sensitivities are obtained for 20 < Z < 40 and Z > 75 and with low proton energies (1–3 MeV). Instrumental parameters and measurement features may be optimized in order to improve limits of detection. The sensitivity of the PIXE analysis is determined by the signal-to-noise ratio (S/N) of detection. The sensitivity of the PIXE analysis is improved by increasing this ratio. The pioneer work of T.A. Cahill, proposes an evaluation of the LOD variation as a function of detector, target, ion beam and measurement conditions.

As a function of the detector parameters, the LOD variation due to:

- Solid angle (Ω), is (Ω)^{-1/2}
- Energy resolution (∆E), is (∆E)^{1/2}
- Count rate (CRM), is (CRM)^{-1/2}

As a function of target parameters, the LOD variation due to:

- Target thickness for given surface density, (τ), is (τ)^{-1/2}
- Characteristic ionization cross-section (σ_z), is (σ_z)^{-1}
- Backing cross-section (σ_Bz), is (σ_Bz)^{1/2}

As a function of ion beam parameters, the LOD variation due to:

- Ion Charge (Z_i), is (Z_i)^{-1/2}
- Ion Integrated Current (Q_i), is (Q_i)^{-1/2}
- The optimum ion velocity is about 0.1 c (c = 3 × 10^8 m s^{-1})

Finally, the LOD variation due to measurement time (t_m) is (t_m)^{-1/2}. Once the main beam features are optimized, it clearly follows that the LOD (i.e. sensitivity) scales as Equation (5):

\[(∆E)^{1/2}(ΩΩτ)^{-1/2}\] (5)

The estimation of the LOD, in the generally accepted formulation, is related to the standard definition of statistical significance of the signal (number of counts in a peak N) with respect to the noise (background counts N_b in the same spectral region). The definition (Equation 6), corrected for situations in which a high enough number of counts is obtained (>10), is

\[N = 3\sqrt{N_b}\] (6)

Equation (6) gives a confidence level of 99.86% for normally distributed measurements. The energy interval within which N_b is determined is generally assumed to be equal to the peak fwhm (full width at half-maximum).

Figure 8 (a) K line and (b) L line LOD (evaluated from Equation (6) over one fwhm of the corresponding peaks) in a thin (1 mg cm^{-2}) carbon target, for 100 µC of total proton charge, at various projectile energies (indicated on each LOD curve). The dashed lines indicate the SEB contribution alone. Detector resolution 150 eV at 5.9 keV, solid angle 0.038 sr. (Reproduced by permission of Plenum Press, from F. Folkmann in: Ion Beam Surface Layer Analysis, eds. O. Meyer, G. Linker, O. Kappeler, Plenum Press, New York, 695–718, 1976.)

Even though Equation (6) is widely used for LOD calculations, other similar expressions are given in the literature. If the background counts N_b are determined as an average from several blank sample spectra, its variance is V_b. The detectable minimum may be defined^{14} for that particular value of counts in a peak N* such that (N* − N_b) equals its standard deviation. With this assumption, the LOD is given by (N_b + V_b)^{1/2}. N* must be ≥10 pulses. Such an expression is suitable for environmental applications, where the measurement of several blank samples is strongly recommended.
3 THE USE OF PROTON-INDUCED X-RAY EMISSION IN ENVIRONMENTAL STUDY

3.1 Preparation of Targets from Environmental Samples

The fundamental importance of adequate sampling procedures in every environmental study must be underlined. Briefly, the sample containers and equipment employed have to be made of suitable material (plastics such as high-density polyethylene (HDPE) and low-density polyethylene (LDPE), and fluorinated ethylene propylene (FEP, Teflon) are preferable). They should be cleaned following a standard procedure used for laboratory ware, then immediately sealed in plastic bags to avoid any possibility of contamination prior to sampling. The same attention needs to be devoted to the equipment used in the sampling procedure. This applies to all items of equipment: to water samplers, to filtration system (used to separate suspended and dissolved fractions in water samples by means of filter membranes), as well as the drill used for sediment and ice-core collection or any other tools used in aerosol sampling. Clean room suits should be worn during sample collection and handling. Several suggestions are given in the literature about sampling procedures in every environmental study must be underlined.

It must be stressed that in trace and ultratrace element analysis all laboratory facilities and procedures must be designed to eliminate any possible contamination.(15) If a so-called “clean room” is not available, good results may be obtained by performing all the target preparation inside a specially equipped laboratory.(12) The laboratory’s main features should be: ordinary dimensions (4 × 4 m), floor covered with a polyvinyl chloride (PVC) sheet, walls and ceiling painted with resistant epoxy paint, access through a double door to ensure perfect closure from the outside. The air inside should be purified by means of class 100 laminar flow clean benches which are operated continuously. The commercially available laminar flow benches forces the air into the work area and in turn expels the air through conventional high-efficiency particulate air (HEPA) filters. Other benches (custom made), more adequately equipped, force air flow into the work area through more than one filter. A satisfactory system includes two conventional HEPA pre-filters and a third special HEPA filter which is 99.999% efficient at 0.3 μm. In addition the air is passed through two activated charcoal cells before being expelled into the lab. To reduce any metal contamination, this bench has been custom made out of natural polypropylene (PP) and polycarbonate (PC). PIXE target preparations are performed on this clean bench.

Throughout the lab operations high-purity water (18 MΩ cm resistivity) is used. This is produced using a Millipore Super Q ion-exchange resin unit. High-purity acids from the US National Institute of Standards and Technology (NIST) as well as high-purity salts and standard solutions from Merck (Suprapur) and Johnson Matthey GmbH, are also employed for target preparations. The assorted sample containers, vessels and lab tools that are used are made of conventional LDPE and FEP. They are either custom-made or supplied by Nalgene. Borosilicate glass (Duran) can be used for higher concentrations. Immersing these containers in a succession of heated acid baths of increasing purity for several weeks ensures cleanliness. The preliminary cleaning procedure can be performed using a Mielabor glass washer and an ultrasonic bath that operates with ultrapure water. Finally, all the personnel in the laboratory wear clean room suits and use LDPE gloves.

Extremely accurate blanks are prepared in order to allow correction for any spurious additions to the samples during both the “in-field” sampling operations and the target preparations. The blank specimens prepared together with the environmental samples are measured under the same experimental conditions. The average blank contribution is subtracted from the concentration measured in the samples, while variance due to the blank fluctuation can be accounted for in the error calculation.(16)

3.1.1 Water Samples

The number of studies dealing with the PIXE determination of trace elements suspended and/or dissolved in water is far smaller than those of aerosols. In great part this has been due to the greater difficulties in preparing targets, even if quantitative evaluations are aided by the use of the internal standard method. The matrix of natural waters may pose problems in the pre-analysis treatment of samples which, especially in the case of ocean water, contain several elements of interest at very low concentrations. Techniques of preconcentration are therefore necessary. In addition, as previously mentioned, solid targets have to be prepared for PIXE analysis, therefore aqueous samples require pretreatment. The preconcentration procedure has to be chosen taking into account the different types of samples: in fresh and seawater the concentrations of the so-called major lighter elements are generally higher than the heavy elements, but in ground and pore water the concentration ratios may be completely different. Rain water, melted snow and ice
behave (generally) as dilute solutions compared to the other natural waters.

In spite of the advantages of using thin sample backings, the preconcentration of natural water may also be performed on thick backings, since these are easier to handle. The sample preparation may be performed either by spraying large sample volumes (up to 1000 mL) or by direct evaporation of smaller samples (10–30 mL) onto thick carbon backings (of the order of 0.3 g cm⁻²). The spraying procedure requires quite large sample volumes, resulting in better DLs of the order of 0.1 ppm of the original specimen. Sample evaporation at a suitably low temperature is certainly preferable because it allows a very high preconcentration without introducing any chemical reagent into the sample, which enables lower DLs. However, problems arise if the sample contains some nonvolatile elements in exceptional amounts, as, for example, is often the case with major cations in surface waters. The presence of a superabundant element on the target always hinders a PIXE measurement as well as affecting the sample preparation because visible crystallization can take place on the backing. Such surface inhomogeneities result in complex matrix effects which are difficult to evaluate. In addition, even if the water deposit is mainly on the target backing surface, a minor part can penetrate into the backing involving target inhomogeneities difficult to evaluate. The sensitivity is impaired by an approximate estimation of matrix effects, with DLs of the order of 0.01 ppm of the original sample.

Methods that use water spraying and water vaporization to prepare thin targets are described in the literature. The water sample to be analyzed is induced to evaporate when placed in a container separated from a vacuum chamber by a thin filter membrane. At complete evaporation the resulting deposit on the membrane may be measured by PIXE, with LOD ranges from 0.1 to 50 ppb (µg kg⁻¹). In another set-up, the water is sprayed into an air system where it forms a fine aerosol, collected by means of an impactor on thin polystyrene film (that will be the target for PIXE). The resulting LOD ranges from 0.1 to 1 ppb. Thin target preparation by means of specimen evaporation has been performed by Laj et al. The procedure employs nonboiling evaporation (lower than 60–70 °C) on liquid samples ranging from 30 to 100 mL. Once preconcentrated to about 100–200 µL, 10 µL of Pd or Y (1000 ppm) solution can be added as the internal standard. The sample is then spotted on a thin backing and evaporated until dryness. Experiments performed on such samples have shown that losses by evaporation are very limited for nonvolatile chemical species. The recovery efficiency of heavy volatile elements is certainly impaired.

In order to obtain a background as low as possible we initially adopted laboratory-made polyvinylacetate (PVA) backings. However its low resistance to attack by acid solutions forced us to select thicker but more resistant backing materials. Another drawback of the PVA backings was the need to remove impurities from them (typically 10 ng cm⁻² of Cu, Ni, Zn and a tenth of ng cm⁻² of Fe and Br), that is quite difficult to achieve without using acids. Acid pre-cleaned PC foils were adopted (the Bayer AG type 1 ng cm⁻², specification which matches Nuclepore filters). The surface density of samples prepared following this procedure from ice and firm specimens, which had been previously melted at laboratory temperatures, resulted typically in 0.3 mg cm⁻² thicknesses (backing excluded), which is at the limits of the thin targets. In Table 1 are reported mean blanks, LOD and analytical uncertainties from samples excited with a 1.8 MeV proton beam, a collected charge of 15 µC, and with a 50 µm Mylar “funny” filter. Mean blanks, LODs and analytical uncertainties (i.e. percent standard deviation of measurement reproducibility) measured with 1.8 MeV proton beam, collected charge 15 µC, and with a 50 µm Mylar “funny” filter. (Reproduced by permission of American Geophysical Union from P. Laj, G. Ghermandi, R. Cecchi, V. Maggi, C. Riontino, Sungmin Hong, J.P. Candelone, C. Boutron, J. Geoph. Res., 102, C12, Nov. 30, 26615–26623 (1997).)

Given the aforementioned problems arising from the high concentration of major elements in natural water, it is necessary to employ selective preconcentration. This also reduces the intensity of background radiation. For this purpose the use of suitable chemical preconcentration procedures and the resulting thin targets are preferred.

There are many methods of preconcentrating aqueous samples and many of them can be used in conjunction with PIXE and XRF. Many treatments use chelating reagents to extract trace metals. The complexes resulting can be extracted into liquid organic phases (several compounds are used for this purpose, a suitable one being ammonium pyrrolidine dithiocarbamate (APDC), as will be discussed in what follows) or absorbed on activated carbon; subsequently, the activated carbon can be removed by filtration and then pelletized. In another application, metal chelates (adding 5 mg of APDC to 500 mL of sample) are adsorbed onto 5 mg of activated carbon, then separated from the water by decanting and
centrifugation. The carbon follows acid digestion (boiling with 35 µL of 8N nitric acid) and finally is spotted onto a thin plastic (PC or polystyrene) backing foil.

The complexes can also be coprecipitated together with a collector element on thin membrane filters. A methodology which involves minimal sample handling is based on the development of a procedure(28) which performs extraction of (trace) elements as carbamates. The technique is based on the high stability of the carbamates of several elements and on their low solubility in water which is mainly determined by pH: the solubility of the carbamate complexes decreases as the pH of the solution increases. When pH values reach a suitable range, from 10% sulfuric acid up to 9, a large number of carbamate complexes precipitate and can be collected by filtration on a thin backing using a coprecipitant agent.

This procedure is suitable for natural waters in which the trace elements are generally already in their more stable state, namely the one complexed by the carbamate chelant. Acidification of the sample at the point of collection or during the sample pretreatment (for pore water or for any aqueous fraction filtered in the field) predisposes most metals to appear in their reduced form as ions. The acidification also breaks chemical bonds of the majority of organic compounds. Obviously this procedure is not recommended for aqueous liquid waste samples which generally require prior treatment to convert the elements into a form readily suitable for analysis. In such cases, other complexing agents like ethylenediaminetetraacetic acid (EDTA) may be discharged in significant concentrations from farms and industrial plants and could result in possible reduction of carbamate extraction efficiency. The use of chelating reagent and coprecipitant on the other hand creates an additional “chemical background” in the sample with characteristic emissions at low-energy. This partially reduces the advantages gained from using thin targets as well as affecting the detection of light elements (as is the case with snow and ice samples).

The largest number of elements, 41, precipitate at pH 9 with sodium diethylthiocarbamate (NaDDTC) as chelant mainly as carbamates but also as carbamates and hydroxides or as hydroxides alone, as a result of the coprecipitation effect.(26) This represents an advantage when very dilute solutions (under parts per billion (micrograms per kilogram) level) are treated, as is the case of open-ocean water. In addition the carbamate hydroxide precipitate acts as a “scavenger” for constituents in solution. However it becomes a problem with fresh water, because, even if NaDDTC does not form chelates with alkaline earth metals, at pH 9 some major cations, like Ca, precipitate following the equilibria of their other salts. This phenomenon strongly affects the features (thickness, uniformity…) of the resulting target. For this reason, even if satisfactory results can be obtained with precipitation at pH 9 with NaDDTC,(14,29) modified target preparation procedures were performed at pH 4 and which made use of the synergistic effect of two chelating agents, NaDDTC and APDC, which also does not chelate the alkaline earths.

Palladium is used as a coprecipitant agent for quantitative carbamate recovery. It can also acts as the internal PIXE standard and is favored for this role owing to the high stability of its carbamate complexes and for its rarity in most environmental specimens. In addition, its K and L lines do not interfere with the detection of the other elements of interest. In the case of Cd and Ag (whose emissions interfere with Pd lines), Cu is used as the internal standard.

Co-precipitation is carried out as follows: 100 µg of Pd (from a 1000-ppm Pd solution in 20% HCl) is added to the sample. Ammonia is added to keep the pH at a value of 4. The carbamate elements are precipitated by adding 1 mL of a freshly prepared NaDDTC APDC (1% q/vol concentration of each) solution which has been previously purified by shaking it with an equal volume of 1,1,2-trichloro-2,2,1-trifluoroethane (Freon). The sample is allowed to stand for a variable period of time, depending on the treated volume (from 30 min to 12 h) and is then filtered through a Nuclepore PC membrane to provide a sample collection area of 0.79 cm². The specifications of the Nuclepore filters are: 0.4 µm pore size, 10 µm thickness, 1 ng cm⁻² surface density and 10⁶ pore cm⁻². The choice of the 0.4 µm as pore size (among the various sizes available) is based both upon filtration efficiency (which has been evaluated to be 99% when using a double filtration technique) and the time needed for sample filtration. Moreover if unfiltered natural water is processed the 0.4 µm pore size ensures good collection of suspended particles (assumed to be greater than 0.45 µm). The collected precipitate forms an apparently homogeneous layer on the filter. Every possible inhomogeneity can be integrated by performing PIXE measurements with a uniformly diffused beam (through a Ni 450 µg cm⁻² foil in the set-up described in Figure 5) collimated to produce a beam size larger than the filtration area on the target.

This procedure has been widely tested and calibrated (see section 3.4) for Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Se, Hg, Pb, Bi, Mo, Y, Ti, Sb, Ag and Cd. The recovery efficiency as evaluated29 and reported in Table 2, remains generally higher than 80% for Fe, Co, Ni, Cu, Zn, Se, Hg, Pb, Ag, Cd, higher than 50% for Ti, V, Cr, Mo, Sb, but lower than 25% for Y and Tl.

3.1.2 Sediment Samples

Sediment and soil solid samples may be analyzed as such, or reduced to slices (if possible), powders or solutions.
Since most samples are not inherently homogeneous, problems may arise in measuring them in the “as-received” state to achieve a representative bulk analysis. The specimens might be desiccated and then pulverized into fine grains: sieves made of silk bolting clothes or nylon which have low metal content are suitable for sieving ground-soil materials. The addition of an internal standard to the sample is then also feasible with a powdered and sieved sample material.

The powdered samples may undergo either a nondestructive or a destructive preparation. In the first case,\(^{(30)}\) a target from soil powdered to micromillimetre fineness is prepared by scattering a few milligrams of soil on a 4 µm Mylar\(^{TM}\) film and using a drop of 0.1 mL of polyvinyl acetate, diluted with acetone, as adhesive. The film of soil results in a homogeneous and adequately thin specimen to meet the thin target thickness limits. In PIXE analysis with 3.5 MeV protons, an Al absorber 50 µm thickness was used to decrease the low-energy background. The most widely used nondestructive methods involve pellet preparation from grained specimens: obviously then, thick targets are prepared. As an example, a soil sample mixed with high-purity graphite into 10:3 soil–graphite ratio was compressed into a disc shape with 0.5 mm thickness and 10 mm diameter. Mylar\(^{TM}\) absorbers have to be used in front of the detector in order to reduce the pile-up effect of low-energy X-rays due to the high concentrations of light elements prevalent in soils. In another study,\(^{(31)}\) a dried and accurately ground and sieved sediment sample (about 5 g) was pressed in a 5 ton press, and pellets of 1 cm diameter and approximately 2 mm thickness were obtained. The elemental concentrations measured ranged from a few ppm to a few percent when the measurement sensitivity was of the order of the PIXE intrinsic LOD.

In the destructive methods, the powdered specimens are solubilized using commonly accepted procedures (not especially performed for PIXE), employing reagents that should be ultrapure grade. The extraction of 10 g of soil may be performed with 50% HCl and 50% HNO\(_3\), then diluted to 100 mL. For PIXE analysis, an aliquot of 0.4 mL of the extract can be dried onto a 4 µm Mylar\(^{TM}\) foil.\(^{(32)}\) Another procedure, especially suited to extract the non-lattice-held fraction from sediment samples\(^{(33)}\) involves the digestion of 5 g of desiccated and ground sediment with 100 mL of 1N solution HCl and agitation for 12 h. The resulting liquid (sediment extract) specimens are preconcentrated as NaDDTC and APDC carbamate on Nuclepore filters, using the procedure previously described for waters. The results are comparable with those of atomic absorption spectroscopy (AAS) analysis. It has to be underlined that the number of studies dealing with PIXE determinations of sediment composition is very small. The Proceedings of the 7th PIXE International Conference contain only one paper on this topic. In fact, even if satisfactorily applied, PIXE cannot completely demonstrate its capabilities in this field. The matrix background, the low-energy X-ray tails and the pile-up pulses worsen the spectrum on each side of the most intense characteristic emissions, and these interferences may result in large inaccuracies in the measurements.\(^{(12)}\)

### 3.1.3 Atmospheric Aerosol Samples

Atmospheric aerosols may be considered to be any liquid matter or solid particles suspended in the atmosphere, and which represent a small fraction, generally below 0.1 part per million by mass, of the total atmosphere.

The study of atmospheric aerosols requires the analysis both of composition of wet and dry fractions and also of particle-size measurements. Concerning the latter, several studies have been performed and protocols optimized on aerosol sampling techniques, that have generally found that particle collection and size-fractionation by impaction, is the most satisfactory technique. Investigations of aerosol composition present considerable difficulties for standard chemical methods since it is very difficult to collect enough mass in each particle size range for analysis, and, also, the concentrations are very low in the liquid fraction.

Among the methods for aerosol analysis based on the use of accelerated particles, the most frequently used is PIXE which has been shown to be a very suitable tool

for the direct analysis of bulk aerosol specimens collected on filters. This is surely the environmental field in which PIXE has found its largest successful application. That results from PIXE’s sensitivity, and also on the simplicity of preparing aerosol targets. In fact, the membranes used in air samplers may be very suitable for immediate PIXE analysis, without further handling: once suitable thin aerosol backings have been selected, and provided an adequate air sampler is used, few problems can arise in preparing aerosol targets for PIXE.

The commercially available air samplers, built to conform to the protocols certified by governments (such as the PM10 specification) in order to check air pollution, can collect a large area aerosol deposit (typically 47 mm diameter) on the backing. Given that a PIXE set-up does not provide so large a beam, the PIXE analysis is obviously limited to small fractions of the collected specimen. Even if more than one target may be obtained from the same specimen, its surface inhomogeneities are not negligible; on the contrary, the use of defocused proton beams larger than the deposit would allow the integration of the whole target surface. It follows that specially designed air samplers can be adapted to produce aerosol deposits of size suitable for PIXE analysis.

The most widely used air samplers are mentioned below; a more detailed review of these devices may be found in Johansson, Campbell and Malmqvist. These samplers collect aerosol particles separated into two or more size classes: the aerosol deposit may be obtained by filtration or by inertial impaction.

The dichotomous aerosol samplers yield two size fractions: among them, the “Gent” SFU (stacked filter unit) (with a suitable inlet that provide a 50% cut-off diameter $d_p$ of 10 µm) separates aerosol by differential filtration into a coarse (2.5 < $d_p$ < 10 µm) particle fraction and a fine particle ($d_p$ < 2.5 µm) collection onto 47 mm diameter membranes; respectively, 8 µm median pore size and 0.4 µm pore size Nuclepore filters are used in most applications. The unit’s air flow rate is typically 17 L min$^{-1}$. The interagency monitoring of protected visual environment (IMPROVE) dichotomous samplers includes a cyclone preseparator that eliminates the coarse particles.

Among the cascade impactors, the unit most commonly used for PIXE is the model I-1 PIXE International Cascade Impactor (PCI). This is a single-orifice impactor with seven plus two (option) impaction stages and a back-up filter stage. The collection surfaces of the various stages are mounted on 25 mm diameter PC rings, and the loading and unloading of these substrate rings in each stage of the PCI is fairly straightforward. The aerosol particles are collected in each impaction stage as a single deposit, which can be easily enveloped by a narrow proton beam (8 mm diameter). The particle size cut-point of the last impaction stage is for 0.25-µm particle equivalent aerodynamic diameter (EAD). Those of extra stages are 0.12 and 0.06 µm EAD. The PCI sampler’s air flow rate is 1 L min$^{-1}$, which is somewhat lower than other impactors.

A rotating version of the micro-orifice uniform deposit impactor (MOUDI) has stage cut-off limits down to about 0.05 µm EAD and operates at 25 to 30 L min$^{-1}$ flow rates. The particles are collected on each stage over a large ring area, so that, as in the case of SFU, only a small portion (<10% of deposit) can be covered by the proton beam during PIXE measurements, thereby decreasing any advantage of the higher flow rate. The Davis, rotating-drum, universal size cut, monitoring (DRUM) sampler has eight slowly rotating drums giving air particle-size fractions of cuts from 0.088 to 9.6 µm EAD. Its vellum-coated Mylar substrate moves at 2 mm per 8 hours. It can operate up to 28 days without attention. Its flow rate is 1 L min$^{-1}$. The DRUM aerosol sample specimen that results from prolonged aerosol sampling is a strip that, for immediate PIXE analysis and best time resolution, should be mounted on a movable frame which can be advanced, on command, two millimeters per step for proton irradiation of each increment.

The small deposit area impactor (SDI) has been designed to collect size-fractionated samples for subsequent PIXE analysis. The SDI is a 12-stage, multinozzle device, with a deposit area with diameter less than 8 mm and accepts the same 25 mm diameter substrate rings as the PCI. The air flow rate is 11 L min$^{-1}$. The experimental aerodynamic cut-off diameters for the 12-stage SDI are given in Table 3.

Various types of thin film can be used as aerosol collection substrates, whereas the samplers that operate by filtration employ various porous filter media. The parameters of commonly used filters are listed in Figure 9. PCI and SDI employ a 1.5 mm Kimfol PC film as collection substrate. In order to reduce particle bounce-off effects, the film is coated with vaseline (especially the larger diameter stages) or paraffin (smaller diameter stages), or apiezon L. The targets from all SDI impaction stages, when irradiated by means of 2.4 MeV proton beams (beam current typically 150 nA, total collected charge 100 µC, funny filter absorber) allow the detection of 22 elements ranging from Na to Pb.

Even if aerosol samples are generally considered infinitely thin, this assumption has to be validated. In fact the inhomogeneous accumulation of particles on the backing is possible, at least in the larger diameter stages, especially with a small deposit area. Given the small quantity of collected material, the target thickness is not significantly improved, but the target handling becomes more critical, with possible loss of particulate from the deposit surface. It may impair the determination of the mass collected, and the subsequent quantitative analysis.

### 3.2 Coupling Target Features and Particle-induced X-ray Emission Measurement Conditions

The sensitivity of PIXE analysis is determined (among other factors) by the S/N of the detected X-ray emission. The PIXE sensitivity is improved by increasing this ratio. In terms of the mass and the energy of accelerated particles, the sensitivity is increased by higher X-ray production cross-sections and low background but both the X-ray production cross-sections and the γ and SEB background increase with increased particle energy, while the PB decreases. Heavier ion beams do not produce significant PB but the resulting GB is more than ten times greater than for protons. The use of a 1–3 MeV beam of protons limits the γ-radiation while the corresponding X-ray production cross-section values are acceptable. SEB radiation may be also reduced taking into account its angular dependence. The background effects can also be minimized by using low Z and thin targets (of the order of 1 mg cm⁻²).

Concerning measurements of the thin targets, it must be stressed that, even if the number of counts in a peak (6), and the related estimation of the LOD, is improved by increasing Q, which may be achieved by operating at higher beam currents, limitations are usually set either by the extent of target damage or by the maximum count-rate that can be handled. Target damage can be decreased, but not avoided, by increasing the target irradiation area and uniformly diffusing the beam to cover this area. Damage can also be decreased by increasing Ω so that, for a fixed CRM, the beam current is minimized. Since the CRM is proportional to the beam current, the peak signal (and subsequently the LOD) is improved when the maximum CRM capabilities of the system are increased. The increasing of the CRM, given the acquisition time for high-resolution detector systems, is limited by increased dead time (and possible pulse pile-up events), relative to the number of emitted X-rays (i.e. to the target composition). The time required for the PIXE analysis of a target from a typical environmental sample (with the set-up of Figure 5) generally ranges from 10 to 30 min. A 10–30-µC integrated beam charge is used, with 10–40-nA current on the target. The majority of the emissions resulting from the abundant light elements and/or the chemicals used for pre-concentration fall in the lower energy part of the X-ray spectrum, and can be attenuated by use of suitable Mylar™ absorbers. If the count-rate does not significantly exceed 1000 counts per second, the detector system operates with dead time less than 5% and with negligible pile-up effect.

The other means to increase Q is by increasing the irradiation time, but that results in more expensive measurements.

### 3.3 Matrix Effects and Interferences

When using non-infinitesimally-thin targets, the evaluation of matrix effects is necessary. Correction factors for X-ray attenuation, for proton energy degradation and for secondary X-ray production (by primary photon absorption) in the samples have been evaluated separately. The yield of X-rays for thin targets may
be assumed to be approximately equal to the product of the yield for intermediate thickness targets and these correction factors. Calculations have been performed for targets with surface densities ranging from 0.5 to 2.5 mg cm\(^{-2}\) prepared from laboratory solutions containing all the calibration elements, from Ti to Bi, in variable concentrations (parts per million to parts per billion), and on environmental samples (precipitated for targets as carbamates at pH 4 with palladium and deposited on Nuclepore filters).\(^{(12)}\) Surface density here refers to the precipitate deposit alone; the backing thickness is excluded. The calculations have also taken into account any accumulation of the precipitate in the Nuclepore filter holes. The effects of secondary X-ray production\(^{(39)}\) was found to be negligible. The ratio between secondary and primary radiation was of the order of 10\(^{-3}\) in the case of the sample composition tested, and thus may be neglected.

The matrix correction for each Z element [MC(Z)] is then limited to the effects of other two phenomena, and is evaluated\(^{(10)}\) as product of a proton energy slowing down correction and an X-ray attenuation correction, separately, as Equation (7):

\[
MC(Z) = \frac{\sigma(E_p)}{\sigma(E_m)} \left( \frac{\mu}{\rho} \right) \frac{\rho d / \cos \zeta}{1 - \exp(-\mu / \rho \rho d / \cos \zeta)}
\]

where \(\sigma(E_p)\) is the cross-section at the particle incident energy \(E_p\), \(\sigma(E_m)\) is the cross-section at the particle energy \(E_m\) that is assumed as “average” energy of X-ray production within the target, evaluated empirically as: \(E_m = E_p - \Delta E / 2\). The energy loss, \(\Delta E\), within the target layer (as presented to the beam) is calculated from the specimen stopping power, by means of published equations,\(^{(40)}\) assuming a linear behavior of energy loss as a function of target thickness, for these thin samples.

The quantity \(\mu / \rho\) is the attenuation coefficient for the characteristic X-rays in the matrix calculated from Thiesen,\(^{(41)}\) \(\rho d\) is the surface density (g cm\(^{-2}\)) of a target of thickness \(d\) and density \(\rho\), \(\zeta\) is the angle of X-ray emission with respect to the target axis (i.e. cos 90° = 1 using the geometry of Figure 5).

In order to calculate the stopping power and attenuation coefficient it is necessary to first establish the matrix composition. When unknown samples are treated, this calculation is performed as follows: the medium–high-Z constituents are measured by PIXE without matrix correction. The main low-Z components arising from the carbamate chelants can be determined indirectly knowing the bonding ratio with chelated atoms. If chemical treatments were not performed, all the target components would be at first evaluated by PIXE without matrix correction. Using an internal standard S (Pd in the experiment), the correction factor applied is the ratio \(MC(Z)/MC(S)\) between matrix correction for the element Z and the internal standard S, thus considerably reducing the weight of the correction factor.\(^{(42)}\)

The multielemental PIXE spectrum having a large number of X-ray emissions involves unavoidable line interferences owing to the limited resolving power of the Si(Li) detector. This problem is adequately solved fortunately by suitable computer codes that include a complete database of all X-ray production phenomena and also optimized experimental values. The interference resolution in PIXE spectra is not, in general, a very critical matter. The more frequently encountered interferences are between the \(K_p\) lines of an element Z and the \(K_p\) lines of element \((Z - 1)\) in the transition element region. For higher-Z elements, the energy differences are large enough to permit the detectors to separate interfering lines. For \(Z \geq 35\) interferences occur between L-lines from heavy elements and K-lines from lighter ones. For \(Z\) around 80, interferences can also occur between M-lines from these elements and K from the lightest detected elements.

Given that the relative K-line intensity from one element is constant, the use of different exciting particles cannot reduce the secondary emission (i.e. the interfering line effects are unaltered). In general no more than 20 elements are simultaneously present in a PIXE spectrum, and this limits the interference problems.

The quantitative treatment of line interferences will be briefly discussed in section 3.4.

### 3.4 Calibration and Measurement Errors

The calibration of PIXE equipment consists of the determination of the X-ray yields for each element of interest; its accuracy depends on a precise knowledge of the basic physical quantities involved and of the experimental parameters. In fact Equation (3) lends itself to absolute analysis; nevertheless many analysts prefer to perform calibration measurements using external standard samples or with the internal standard method. In the case of thin samples, the sensitivity may be determined by measuring the \(K_p\) or \(L_p\) X-ray yields (as a function of Z) per microcoulomb of proton charge per unit areal density, employing thin, uniform standard targets, and a particle beam normal to the target surface (Equation 3). These external standard specimens are commercially available, the most widely used being from the MicroMatter Company. They consist of very thin, certified, layers (20–50 µg cm\(^{-2}\)) of various elements evaporated onto Mylar\(^{\text{TM}}\) or Nuclepore membrane. The accuracy of the estimation of the sensitivity curve with a large number of points has been found\(^{(6)}\) to be better than 10%. Loss of volatile elements (Hg, As, Br) may occur during proton bombardment, but was found to be negligible\(^{(11)}\) (apart from Br) with beams of tens of nanoamperes or less.
Several laboratories of applied nuclear physics have prepared their own thin external standards by means of element evaporation or similar techniques. The reliabilities of these standard specimens are in many cases of the highest level. Calibration measurements\textsuperscript{12,20} have been performed with satisfactory results using standard thin targets prepared at the INFN Laboratory at Legnaro, Padova (Italy). These were prepared by vaporization of elements onto PC backings. The calibrated elements are: Na, Mg, Al, Si, P, S, Cl, K, Ca, Ti, Cr, Mn, Fe, Co, Cu, Ni and Zn. An alternative approach consists of the use of standard solutions pipetted in micro-drops and left to dry onto a thin backing (Mylar\textsuperscript{TM}, Nuclepore...). The deposit has to be completely covered by the proton beam, whose cross-sectional area must be also measured. There are advantages to choosing the elements introduced in the target and to deposit them on the same backing used for environmental samples. Problems may arise if dried solutions form a nonuniform deposit with clumps of crystals on the backing. Given that the standard specimens must be as similar as possible to the features of the environmental samples, it follows that this procedure is preferable for aerosol analysis.

The use of internal standards is surely to be preferred when the environmental specimen must be chemically treated to obtain a suitable PIXE target which is the case for water samples. In fact after addition the yield \( N(S) \) of the standard element \( S \) will be subjected to all the same losses as the sample followed during the target preparation procedure. The yield \( N(Z) \) of any other elements can then be experimentally determined with respect to recovery of the internal standard.

From Equation (3) it follows that when the internal standard is added, the determination of the ratio \( N(Z)/N(S) \) in a given target does not require the knowledge of some physical quantities: \( N_p, \Delta Z \). The mass ratio \( M(Z)/M(S) \) may be considered equal to the ratio \( C(Z)R(Z)/C(S)R(S) \), where \( C \) is the concentration of element \( Z \) and the standard in the original water samples and \( R \) the percentage recovery of the internal standard. The statistical processing\textsuperscript{9} of several calibration measurements made under the same experimental conditions leads to the evaluation of a parameter \( K(Z, S) \) that relates the ratio between number of X-ray counts \( N_C(Z) \) in the peak of an element \( Z \) and the number of X-ray counts \( N_C(S) \) in the standard peak to the corresponding concentration ratio \( C(Z)/C(S) \) (Equation 8)

\[
\frac{C(Z)}{C(S)} = \frac{K(Z, S)N_C(Z)}{N_C(S)}
\]  

where it is obviously assumed that a linear behavior of yields exists within the concentration range involved. The parameter \( K(Z, S) \) represents the ratio between the other terms of Equation (3), with recovery efficiency included, for both the standard and the element to be determined.

The calibration of the procedure for target preparations from water samples by means of element precipitation as carbamates (section 3.1.1), has been calibrated with mono- and multielemental solutions (for both fresh and artificial seawater) and with reference materials for a wide group of elements (Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Se, Hg, Pb, Bi, Mo, Y, Ti, Sb, Ag, Cd), in the parts per trillion (nanogram per kilogram)–parts per million concentration range, after preconcentration of variable sample volumes ranging from 500 to 15 mL\textsuperscript{9,14,29} Satisfactory replicate results have been verified, with measurement errors generally lower than 10%. Problems arise for Mn, whose precipitation as a carbamate is quantitative at pH greater than 6, and for Ti, Cr and Y, which are extractable mainly as hydroxides. The reproducibility of the PIXE measurement of a given target under the same experimental conditions is quite high: the uncertainty, \( \epsilon \), coming from the slight variability of the set-up parameters (such as the proton flux) may be experimentally estimated (generally \( \epsilon < 5\% \)).

The evaluation of another part of the measurement errors in PIXE analysis can be directly performed by the computer codes that examine the spectrum. In fact, each peak fitting system estimates an uncertainty that has to be accounted for in error evaluation: the formulation of this fit error, \( \epsilon_f \), depends on the particular spectrum deconvolution procedure used by the code.

For the specimens (such as aerosols) that do not require a target preparation procedure, the PIXE measurement error may result from the contribution of \( \epsilon_b \), of \( \epsilon_e \) and of the variance \( V_e \), of a suitable number of blank samples (backings) measured under the same experimental conditions. When a target preparation procedure is needed, the measurement, \( \epsilon \), error expression may be expressed as Equation (9):

\[
\epsilon = V_b + \epsilon_e + bC(Z)
\]  

where \( b \) is the average percentage error of the measured concentration, \( C(Z) \), evaluated from calibration measurements at the same concentration range of \( C(Z) \), and includes \( \epsilon_e \). The values of \( b \) and of experimental calibration parameters (such as \( K(Z, S) \) involved with the internal standard method, Equation (8)) may be determined\textsuperscript{9} by a system of nonlinear equations which can be solved by a quick converging iterative process. One equation can be obtained by imposing the condition that the relation shown in Equation (10):

\[
\sum_{i=1}^{n} \frac{\Delta C(Z)_i}{\epsilon_i}^2
\]
be a minimum (best fit), where $\Delta C(Z_i)$ is the difference between theoretical and measured concentrations of the $i$th sample, $i$ ranging from 1 to the number $n$ of the calibration samples analyzed. The quantity $\varepsilon_i$ is the error (Equation 9) for the same $i$th sample. A second equation is obtained by imposing the condition that Equation (10) at minimum be equal to the degrees of freedom $(n - 1)$.

### 3.5 Detection Limits and Ranges

The PIXE intrinsic sensitivity, the LOD calculation and its improvement by coupling target and measurement features, has been previously detailed. The LOD should be quoted with information of integrated beam charge, experimental geometry, energy resolution and background interval. The experimentally evaluated LODs from water and aerosol specimens are here reported. In the case of water samples preconcentrated by elemental precipitation as chelates, the procedure suggested by\(^{27}\) gives the LODs for marine water and blank listed in Table 4. Unfortunately, information about the measurement parameters are not reported in this work. The LODs calculated for water samples precipitated as carbamates\(^{12}\) and obtained using $15 \mu$C of 1.8 MeV protons for an averaged blank spectrum and for the Nuclepore backing alone, using K X-rays, are reported in Figure 10. The LOD for the Nuclepore samples (calculated using the external standard calibration method) are comparable with the expected values in a 1 mg cm\(^{-2}\) carbon target,\(^{45}\) for the same integrated charge. The LOD values for the blank are generally close to the values obtained for Nuclepore, even if they are

Concentrations, percent recoveries and LODs for some elements in seawater and in blanks prepared following the same procedure used for seawater samples. Only five elements could be detected in blank samples, and four of them were detected in the seawater sample. The relatively large concentration of Fe increases the background and hence affects the detection of neighboring elements (Mn, when close to the DL, and mainly Cr). (Reproduced by permission of Elsevier from E.M. Johansson, S.A.E. Johansson, Nucl. Instrum. Methods Phys. Res. B, 3, 154–157 (1984.).)

The minimum detectable limit for a 2 ng cm\(^{-3}\) PIXE analysis of some air samplers\(^7\) are: SFU 0.6 ng m\(^{-3}\), IMPROVE 0.14 ng m\(^{-3}\), DRUM 1.1 ng m\(^{-3}\), MOUDI 3.3 ng m\(^{-3}\).

The DLs as a function of $Z$ for PIXE analysis of PCI and SDI air samplers are given in Figure 11 (2.4 MeV proton beam, 300 nA cm\(^{-2}\), corresponding to 90$\mu$C charge for 0.5 cm\(^2\) beam size).

These results confirm that the LOD variation with $Z$ follows substantially the rapid decrease in cross-sections mitigated by the fluorescence yield and by the background shape, and is slightly affected by the recovery efficiency of the target preparation procedure (if applicable).

### 4 INTERPRETATION OF PROTON-INDUCED X-RAY EMISSION SPECTRA OF ENVIRONMENTAL SAMPLES

The analysis of the PIXE spectrum is performed by computer codes that deconvolute the spectrum in order to calculate peak areas. Briefly, for proton-induced X-ray emission, these codes\(^{44}\) (the most widely used are AXIL, HEX, NANOLEX, PIXAN, SESAMIX and their further improvement, and more recently GUPiX) apply linear or nonlinear (or both) least squares fit (LSF) fitting procedure. The background (to
Figure 11 The DLs for K X-ray emissions (evaluated from Equation (6), neglecting the contribution from blank variability) as a function of Z for PIXE analysis of PCI and SDI air samplers, for 2.4 MeV proton beam and 300 nA cm$^{-2}$, corresponding to 90 µC charge for 0.5 cm$^2$ beam size. 5 METHOD DEVELOPMENT FOR ENVIRONMENTAL PURPOSES

The possibility of coupling PIXE analysis with other techniques in the same irradiation chamber will be discussed in section 6.3. The high-energy proton microprobe outlined here represents a considerable increase in proton PIXE power and flexibility in the environmental field.

5.1 Proton Microbeam Application

In typical microbeam equipment,$^6$ a beam from the accelerator passes through an analyzing magnet which stabilizes the particle energy, and is then defined by a collimator, with an aperture whose diameter is in the range 10–100 µm. This aperture is placed at a corresponding element by means of the X-ray yield. The commercial availability of continuously evolving computer codes such as GUPiX$^{65}$ represents a great advantage for PIXE workers. Based on a large database and a deep knowledge of the physics of X-ray productions by accelerated protons, this code may satisfactorily examine PIXE spectra from each set-up whose technical and experimental parameters have been accurately determined. The peak intensity errors (for 26 ≤ Z ≤ 83) through fitting of various spectra are estimated to within <10% for peak areas less than 500 counts and <5% for larger peak areas.

A different approach has been applied to trace element analysis in thin targets which are prepared from chemically pretreated liquid samples. The SPECTRE program$^{16}$ is based on experimentally evaluated parameters and calibrations and operates with linear LSF. The background shape is taken as the averaged spectrum from several blank targets measured in the same PIXE region, thus including the chemical treatment background. The peak shape is gaussian. Escape lines and first-order pile-up effects are taken into account. Relative intensities of X-rays and transmission through the whole set-up have been experimentally evaluated by measuring reference targets. The peak identification is performed (without previous instructions or assumptions) among all the elements for which the recovery of the target preparation procedure is significant. The X-ray yields to be used are obtained from calibration measurements of water samples that followed the same chemical treatment. The concentrations in the original water sample are then calculated. Even if suitable for a restricted number of applications, this code provides reliable determinations of trace and ultratrace elements, with fit error generally <5% for peak areas of about 100 counts or greater.
focusing point where the beam diameter is a minimum: the divergent beam is then further focused by a lens system (usually a magnetic quadrupole). The aperture (more commonly called crossed microslits) is a critical component in a microbeam line, because of scattering of the particles by the edge of the slits. It can give rise to a halo around the central beam that diminishes the resolution. At the end of the beam line, in the vacuum irradiation chamber, scanning over the specimen surface is accomplished by moving either the specimen or the beam. A microscope allows the optical viewing of the sample. A PIXE X-ray detector and the electronic devices for spectral analysis are the same as are used for diffused-beam PIXE. The layout of the microbeam irradiation chamber at INFN Laboratory of Legnaro (Padova, Italy)\(^{(46)}\) is depicted in Figure 12.

**Figure 12** The irradiation chamber of the proton microprobe at INFN Laboratory of Legnaro (Padova, Italy). 1, Reaction chamber; 2, PIXE Si(Li) detector; 3, magnet quadrupole lens; 4, micrometers for lens reg.; 5, stereo microscope; 6, Rutherford backscattering spectrometry (RBS) annular detector (internal diameter = 4 mm); 7, microscope mirror center; 8, target holder; 9, Faraday cup; 10, sample changing port; 11, detector filter holder. (Reproduced by permission of Elsevier from P. Boccaccio, D. Bollini, D. Ceccato, G.P. Egeni, P. Rossi, V. Rudello, M. Viviani, *Nucl. Instrum. Methods Phys. Res. B*, 109/110, 94–98 (1996).)
Most applications of microbeam PIXE are for mapping spatial elemental concentrations. A specimen is moved in small steps (positional reproducibility better than 1 μm) in two orthogonal directions perpendicular to the fixed beam or by linear scanning. A major problem with sequential scanning is specimen heating. Alternatively, the beam may be deflected in two orthogonal directions onto the surface of a fixed specimen. This method is mechanically simpler and reduces sample heating since the scanning is fast. A PIXE spectrum is recorded at each position.

The spatial resolution of the best PIXE microbeams is about 1 μm, but it is not comparable with electron microprobe resolution, which is better than 0.1 μm for surface analyses. In targets thicker than a few tens of micrometers (which includes the most samples) electron scattering broadens the beam, and the resolution of the electron microprobe is considerably impaired; given that the penetration of electron beam is about 10 μm, this is also the effective lateral resolution. The proton microbeam resolution is maintained (1–2 μm) for tens of micrometers of penetration depth, making this technique preferable for specimens thicker than a few micrometers.

The sensitivity of proton microbeam (proton μ-PIXE) may be scaled from proton-induced X-ray emission sensitivity, taking into account that the LOD is inversely proportional to the square root of the integrated charge (Equation 5). In proton μ-PIXE the current in the target (typically hundreds of picocaneperes) is one or two orders of magnitude less than in the diffused beam technique. In addition, assuming the same total X-ray measuring time, in the scanning mode, the total collected charge is divided among all the scanned positions. If for a PIXE measurement generally a few minutes are required, proton μ-PIXE requires longer measuring times (some hours to obtain a spatial map). With the same assumptions of section 2.4 for operating parameters, the proton μ-PIXE DLs that result are of the order of 10 ppm of the exposed target, which are better than the LOD for an electron microprobe analyzer, which is about 0.1%. Trace elements are seen only with the proton μ-PIXE: the small size of the irradiated area (few micrometers diameter) allows detection of absolute quantities of 10^{-15}–10^{-16} g. In addition, given the energy of the proton beam (some megar electron volts) compared to the electron microprobe (typically a few of tens of kiloelectron volts), and the high intensity of the electron bremsstrahlung emission, the detection of elements heavier than (about) Z = 30 by means of their K-lines is possible only with proton μ-PIXE.

The use of a proton microbeam to map the elements in a specimen involves the problem of maintaining, in the target, the spatial distribution of the original sample. It may be particularly difficult in biological applications, where the structure even of single cells is examined.

In geological applications thin slices of minerals are readily available. In the environmental field, proton μ-PIXE may be a very powerful tool in the investigation of major and trace elements in aerosol particles. The microbeam map of a portion of an aerosol deposit on a thin backing allows the determination of the elements’ associations and relative abundances, providing an immediate characterization of the studied aerosol. The image of a single grain of at least some micrometers size can be studied; however, the resolution is probably better with the SEM/EDAX technique, which is preferable for any morphological study.

6 COMPARISON WITH OTHER SPECTROMETRIC TECHNIQUES

Comparison of various features of proton-induced X-ray emission with those of other techniques are included in this paper, in order to support an understanding of its capabilities and limits. Here are reviewed briefly the other major spectrometric techniques and methodologies which are complementary to proton PIXE.

6.1 Methods that use Particle Beams

Deuteron beams are little used in PIXE (and never in environmental analysis), mainly because of the emission of neutrons from nuclear reactions. α-particles, which do not produce PB in specimens with matrix light elements having Z/A = 0.5, may be used in place of protons with very good results, especially when high sensitivity is not required. α-particles of 10–20 MeV (which are often used) provide a high GB contribution to the background, thus limiting the sensitivity. In addition, the large energy loss of α-particles causes appreciable target damage by heating. The beam intensity must then be limited, which offsets the advantage of the higher α X-ray-production cross-sections.(7,11) A study(47) of high interest indicates that for thin organic specimens 5 MeV helium ions provide a significant improvement of LOD compared to 1–3 MeV proton beam.

Heavy ion beams of few hundreds of kiloelectron volt energies have been successfully used in surface analysis given their large X-ray-production cross-sections. The small number of studies performed with heavy ion beams (7Li, 12C, 16O, 28Si, 80Se) at energies of the order of tens of megar electron volts do not indicate any particular advantage for trace element analysis compared to the use of proton beams. A major problem with heavy ion PIXE is the GB emission: in Figure 4 data are reported for helium and oxygen projectiles (in comparison to protons at equal particle velocities). Given that only the protons generate PB while all three ions generate SEB, the
intense backgrounds (more than ten times greater than for protons) of the helium and oxygen ions at higher energy depend on \( \gamma \)-radiation from nuclear reactions in the specimen. Other problems are the low-energy continuum background from the filling of molecular orbital vacancies and the associated increased spectrum complexity.\(^{7,11}\)

Electron microprobes were compared with proton \( \mu \)-PIXE in section 5.1.

### 6.2 Other Technologies

XRF\(^{48,7}\) induced by X-ray tubes has some common features with proton PIXE: it allows multielemental, fast, nondestructive analyses of solid specimens. XRF is not an alternative to PIXE in the determination of trace elements in thin samples, such as environmental ones. The sample characteristics cannot be neglected in sensitivity evaluations; proton PIXE LODs for thin, light matrix targets are in the 0.1–1 ppm range (for transition elements and heavy metals up to lead), while for XRF the corresponding LODs are 1–10 ppm, and the difference is more pronounced in absolute terms (a few picograms can be detected by PIXE, and hundred nanograms for XRF). The situation is quite different for thick specimens, such as mineralogical specimens, soil or sediment pellets, where proton PIXE and XRF are comparable, the latter being preferable for heavy-element matrices.

A significant development of XRF is the total reflection X-ray fluorescence (TRXRF) technique. This technique reduces the main source of spectrum background (scattering of primary radiation from the specimen support) by using an incident angle less than the critical one, so that total reflection results with very little scattering. This method allows absolute DLs of a few picograms, but requires that a thin (<10 \( \mu \)m) sample layer is spread out over the entire quartz plate surface. In diluted natural water (rain, melted snow), sub-parts per billion concentrations may be detected. Groundwater or marine water (rain, melted snow), sub-parts per billion concentrations correspond to sample concentrations ranging from 0.1 to 30 ppm. The interferences are also more complex owing to the larger number of emitted lines and severe matrix interferences.

The requirement for liquid specimens to be injected into the instruments led to the common use of these techniques in environmental studies of natural waters, snow and ice. Trace element determination at the parts per trillion level has been performed using AAS by several authors in sea\(^{50}\) and fresh water and in polar snow\(^{51}\) and ice samples. The analysis of solid material involves complex preparation, with possible contamination or changes of the sample, which is destroyed during the analysis. A variant, electrothermal atomization atomic absorption spectroscopy (ETAAAS) deals with solid specimens, providing better LODs than ICPAES, but matrix effects are very appreciable, and, additionally, it requires longer analysis times.

Coupling ICP excitation with mass spectroscopy (ICPMS) reduces the problem of spectral interferences, while the matrix effects become more serious with increased concentrations of major elements, that can interfere with the detection of trace elements. Nevertheless this technique allows the detection of almost all the elements, and has no high variation in sensitivity from...
one element to the next. In addition, the cost of high-resolution ICPMS instruments reduces the availability of this equipment.

Finally, neither NAA nor optical spectroscopy methods offer a microbeam capability.

This short review shows that, in environmental applications, other methods can compete with PIXE in water and sediment analysis, while for air pollution particulates, the PIXE technique is surely the most suitable in terms of analytical capability, sensitivity and economy.

6.3 Combined use of Particle-induced X-ray Emission with Other Techniques

Some complementary techniques may be used simultaneously with proton PIXE, with a suitable set-up and appropriate set of detectors placed in the irradiation chamber. Particle elastic scattering analysis (PESA) is based on the dependence of forward scattered particles on the Z of the scattering target atom and on the angle of diffusion. A multielemental analysis may be performed by measuring the energy spectrum of particles scattered at fixed angles, at least for light elements $Z \leq 20^{(8)}$ hydrogen included, by proton–proton scattering. PESA entails more stringent restrictions about sample thickness. It is currently used with proton PIXE$^{(7)}$ to perform hydrogen measurements in air particulate filters, and absolute accuracy of 3% has been achieved with sample thickness below 1 mg cm$^{-2}$, which is the surface density range of almost all the aerosol filters.

Particle-induced $\gamma$-ray emission (PIGE) is based on the detection of particle-induced $\gamma$-rays. Given the light elements ($Z < 20$) responsible for these emissions (see section 2.1), PIGE may be used in conjunction with proton PIXE for the detection of light elements of interest such as fluorine. Its use for the light elements measurable also by proton PIXE has to be carefully assessed, given the better PIXE sensitivity and the quite high cost of PIGE.$^{(7,8)}$

RBS is based on the elastic backscattering of incoming ions by nuclei in the sample. RBS allows the determination of the mass of the scattering nuclei and the depth of the nuclei in the target. RBS is used in combination with PIXE$^{(7)}$ for matrix determination, light element determination and depth profiling. The RBS technique is particularly useful for thin specimens (such as aerosol filters) to detect light elements of especial interest (carbon, nitrogen, oxygen). Its detector has to be placed as close as possible to 180°, near the beam axis at a backward angle.

Finally, scanning transmission ion microscopy (STIM)$^{(52)}$ may be performed on a light ion beam that has passed through a sufficiently thin target, by means of a detector placed behind the sample at 0° to the beam. The energy loss caused by ion–electron interaction provides information about density, thickness and structure of the sample. If a scanning microprobe is utilized, STIM provides transmission images. STIM at 0° is highly efficient with low ion currents, which enables spatial resolution of the order of 50 nm,$^{(7)}$ but this condition is not compatible with simultaneous use of RBS and PIXE. Satisfactory results with RBS, PIXE and STIM in biological and aerosol particle studies have been obtained placing the detector at 15°–25° to the beam axis, even if this use of STIM impairs its precision and provides the identification only of the main structures of the target.

Vigorous and thorough programs of quality assurance (QA) are vital to ensure that environmental analysis studies yield results which are trustworthy, scientifically credible, and of known quality commensurate with their intended use. Mistakes in any step of the environmental analysis process can result in a substantial increase in random and nonrandom errors. Poor design of an environmental analysis program or failure to adhere to good scientific practices (GSP) for every step of the environmental analysis process can result in compromised or even meaningless results. Therefore, a holistic approach must be taken to ensure adequate QA is implemented for each and every step of the environmental analysis process, from initial study design through final information reporting. However, there is a substantial economic cost to
incorporate QA on such a thorough and comprehensive basis. Therefore, QA efforts are unlikely to succeed unless management is committed to the value of these efforts. Increased recognition of the importance of QA, plus broadened international adoption of harmonized standard QA methodologies, has substantially improved the reliability of environmental analyses. QA ensures that environmental monitoring results are compatible with project goals, are comparable between different agencies, and maintain a high degree of scientific credibility. The key elements of QA programs include comprehensive planning, defined data quality objectives (DQOs), thorough training of personnel, standard operating procedures, detailed documentation, timely resolution of problems, regular reporting, routine independent audits plus regular challenges of study elements.

1 INTRODUCTION

1.1 Introduction to Quality Assurance

Resource management decisions underpin our environmental, economic, and industrial prosperity. It is important that monitoring results upon which such decisions are based be trustworthy. Therefore, every environmental study should include a QA component to provide confidence that the study results are credible. The key elements of the QA component of environmental analysis studies include:

- comprehensive planning;
- documentation of study objectives;
- documentation of study methodologies;
- thorough training of personnel;
- comprehensive record keeping;
- timely identification and resolution of problems;
- regular reporting of results;
- routine challenge of study elements; and
- regular independent audits to ascertain whether study elements are in control.

There are a number of somewhat different approaches to QA. While most people would agree with the concept that environmental measurements should be reliable, there is often debate as to how best to achieve this goal at an affordable cost. Nonetheless, there is a broad consensus that QA is a critical consideration for every element or activity of the environmental analysis process.1,2

There are different reasons why samples are collected. Samples may be taken to determine compliance with government regulations (legal sampling). In other instances, samples might be collected to determine the presence or absence of some particular contaminant and also the extent of its dispersal in the environment (environmental monitoring). Sometimes samples are collected to determine change in environmental conditions or change in levels of contamination (trend monitoring). The specific purpose underlying environmental analysis programs often dictates the choices as to sampling methodology, sampling sites, sample collection strategy (random, systematic or judgmental), sample frequency, types of container, and intensity of QA effort. Therefore, it is important that the specific purpose of environmental analysis programs be defined before any routine process of sample collection and sample analysis is established. DQOs must be defined in the initial project planning stage. Field personnel, laboratory analysts, data users, statisticians, and systems analysts should be jointly involved from the study onset, since each has a critical role towards achieving the collection of results which are both useful and credible.

It should be emphasized that QA for the field sampling aspects of environmental analyses and for the laboratory analysis aspects are two distinctly separate but interrelated activities. The first responsibility of field personnel is to ensure that samples collected truly are representative of the ecosystem being sampled. The first responsibility of laboratory analysts is to ensure that the analysis results accurately describe each sample received. Sampling errors and analytical errors often occur independently of each other. High analytical precision in a laboratory will not compensate for errors made during sample collection. Careful collection of representative samples in the field will not compensate for poor precision in the laboratory.

1.2 Economics of Quality Assurance

From a "total quality management" point of view, quality cost is usually described as a framework for analyzing an organization’s quality policy. On the one hand there is the cost of ensuring (prevention cost) and of assuring (appraisal cost) that a product meets a certain quality standard. Balanced against these costs are the costs when this standard of quality is not achieved (failure cost).

The QA component of an environmental analysis study seeks to increase the likelihood that the investment cost of collecting and analyzing samples returns data both credible and useful for the intended purpose. QA also seeks to offer some guarantee or assurance that monitoring data collected by two or more agencies will be comparable. Certainly the main benefit to environmental analysis studies derived from QA is enhanced credibility of results to colleagues, peers, and clients. The main disadvantage is a significant increase in overall costs, often by 10–20% or more. Most of this additional cost is the
direct result of the costs associated with control samples, audit samples, standard reference materials (SRMs), and equipment preventive maintenance. Nonetheless, the cost of adding QA is much less than the cost of redoing a study, and very much less than costs associated with erroneous resource management decisions made upon dubious or flawed information. Both the costs and benefits of QA have been tabulated by Taylor, as compiled in Table 1. Although Taylor’s tabulation of costs and benefits were only for the laboratory analysis portion of environmental analysis studies, nonetheless these costs and benefits equally apply to the entire environmental analysis process.

Table 1 Costs and benefits of QA. (Reprinted with permission from J.K. Taylor, Quality Assurance of Chemical Measurements, CRC Press, Boca Raton, FL, 1987. Copyright CRC Press, Boca Raton, FL.)

| Direct costs                                                                 |
|                                                                            |
| Test materials                                                             |
| Standards                                                                  |
| Quality assurance equipment – test instruments                             |
| Analysis of QC/quality assurance samples                                   |

|                                                                            |
| More efficient outputs                                                     |
| Fewer replicates for same reliability                                     |
| Fewer do-overs                                                             |
| Greater confidence of:                                                     |
| Staff                                                                      |
| Laboratory                                                                 |
| Customers                                                                  |

| Intangible benefits                                                        |
|                                                                            |
| Promote external image                                                     |
| Improve internal image                                                     |
| Promote client confidence                                                  |
| Add credibility to results                                                 |
| Prevent hasty decisions                                                    |
| Minimize indecision                                                       |
| Eliminate unnecessary redundancies                                        |
| Promote continuity of effort                                               |
| Provide for retention of vital records                                    |
| Set forth goals and objectives                                            |
| Provide guidance to staff                                                  |
| Provide basis for training                                                 |

1.3 Quality Control and Quality Assessment

QA consists of two separate but complementary aspects, quality control (QC) and quality assessment. For this reason, QA sometimes is referred to as quality assurance plus quality control (QA/QC). QC includes all those activities having the purpose of controlling the quality of produced information to ensure it is adequate for the purpose intended. Quality assessment includes all those activities undertaken to confirm that the QC activities were performed effectively. It is useful to consider that QC refers to those aspects of QA which are fully under an investigator’s control (such as instrument calibration), whereas quality assessment refers to those aspects of QA which are not under an investigator’s control (such as independent audits). To eliminate the confusion resulting from the similar terms “quality assurance” and “quality assessment” and their identical acronyms, some organizations prefer the terms “internal QC” (synonymous with “QC”), and either “external quality assessment” or “quality surveillance” (both synonymous with “quality assessment”). In this article, the acronym QA is restricted to the term “quality assurance” except when it occurs within the double acronym QA/QC. It should be noted that some authors use the term “QA” both as defined above and additionally as synonymous with “quality assessment” (there is an example of this in Table 1).

1.4 Reasons for Concern

Experienced scientists [e.g. Mesley et al., Rose and Smith] continue to warn that a significant proportion of environmental data sets are not fit for the purpose intended. Unreliable data sets continue to be accumulated in the literature and on electronic databases. Ultratrace analyses are particularly vulnerable to serious error. King states that “This is both a costly and a dangerous problem which could get worse as the demands of society increase”. Additionally, many present-day environmental data sets will be of interest in future decades and centuries. The credibility of present-day data sets to future scientists requires that trustworthy data be unambiguously distinguishable from untrustworthy data. Also, since equipment and methodologies are changing at a rapid pace, future scientists must be able to ascertain whether or not various different methods employed over time are comparable to each other. Both reliability and comparability assessments will require convenient (i.e. electronic) access to permanent archives of complete chronological records including methodology details, plus results from comprehensive programs of QA.

1.5 Scientific versus Administrative Studies

An unfortunate fact of the real world is that studies do occur without QA. Reports from studies with QA and
reports from studies without QA can look very similar in appearance, particularly to nonscientists. Clark\(^{(7)}\) refers to studies having comprehensive QA as “scientific studies” and to studies without QA (or with inadequate QA) as “administrative studies”. Clark\(^{(7)}\) notes his experience that scientists and administrators have very different points of view as to the relative value of scientific versus administrative studies, as indicated in Table 2. Administrators often consider QA to add unnecessary project costs, whereas scientists view QA as essential to keep project results scientifically credible. It is important that both scientists and administrators recognize these differences in viewpoint. It cannot be emphasized too strongly that studies that lack QA also lack genuine credibility, and put at risk the very environmental resources the studies are meant to protect. Management commitment to QA is essential for QA/QC efforts to succeed.

Often it is marketplace arguments, not scientific merit, which bring administrators to endorse QA. Environmental remediation costs, environmental liability insurance fees, lawyers fees for court appearances, regulator fees and fines, impacts of adverse public relations – all are expensive costs. QA is the best strategy to avoid or minimize such costs. There is increasing recognition that QA genuinely can contribute to the “bottom line” by reducing overall operating costs and vulnerability to regulatory fines. It can be argued that international recognition of QA can be rewarded by worldwide economies of the order of magnitude that can come from the reduction of QA efforts (from former estimates of $100 billion to $30 billion for the U.S. alone)\(^8\). QA is best accomplished by the decision of the whole organization for QA in place and successfully implemented. It should be noted that some scientists employ the term “environmental analysis” to refer solely to laboratory operations concerning the analysis of environmental samples.

2 ENVIRONMENTAL ANALYSIS

“Environmental analysis” is the overall process of sampling or monitoring environmental systems so as to derive understanding of environmental quality and ecosystem operating mechanisms. Sample collection and laboratory analysis each forms only part of the overall process of environmental analysis, as described by Porter et al.\(^{(8)}\) (Figure 1) and by Clark and Whitfield\(^{(2)}\) (Figure 2). Environmental analysis itself is a key component of the resource management (sometimes called “environmental management”) process. In order to have credible results produced, every component of the environmental analysis process must be documented to have a program of QA in place and successfully implemented. It should be noted that some scientists employ the term “environmental analysis” to refer solely to laboratory operations concerning the analysis of environmental samples.

2.1 Good Scientific Practice

It is easy to challenge the credibility of environmental studies. Environmental samples are collected under imprecisely controlled conditions, but the environments from which these samples are collected are both heterogeneous and dynamic. Also, samples might be unintentionally modified at any of the steps that make up the environmental analysis process. To ensure environmental data are scientifically credible, environmental scientists must document in detail their adherence to “GSP”. GSP (sometimes called “accepted scientific practices”) are those operating procedures that have been accepted by scientists of authority to be the minimum requirements to promote quality and integrity of scientific findings and results. GSP include detailed documentation of objectives, of experimental design, of methods and procedures employed, of hypotheses tested, of unusual events, of deviations from regular practices, of results from ongoing evaluations of bias and precision, and of results from regular independent audits. Together these records provide a complete chronological record to support the validity of the environmental analysis results.

The literature includes papers describing GSP for environmental analysis studies in general.\(^{(1,2,9)}\) The literature also contains numerous papers describing GSP for each of the elements of environmental analysis studies, particularly program design,\(^{(5,10–13)}\) sample collection and handling,\(^{(14–16)}\) laboratory analyses,\(^{(17,18)}\) data collection and handling,\(^{(14–16)}\) laboratory analyses,\(^{(17,18)}\) data reporting,\(^{(8,19)}\) data assessment,\(^{(13,20)}\) and statistical data

Accurate understanding of environmental quality conditions

Figure 1 Flow of information in an environmental analysis system. Note that sampling and laboratory analysis form two parts of a series of processes. (Reprinted with permission of the American Chemical Society from P.S. Porter, R.C. Ward, H.F. Bell, ‘The Detection Limit’, Environ. Sci. Technol., 22(8), 856–861 (1988). Copyright 1988, American Chemical Society) (modified slightly from the original figure, which pertained to water quality systems).

evaluation\(^{\text{(11,21)}}\) (this is just a small selection of citations from many hundreds of papers). Synonymous terms for “GSP” regarding subelements of the total assay process include “good monitoring practice”, “good measurement practice”, “good sampling practice”, and “good laboratory practice” (GLP). The flowchart in Figure 3 shows the integral relationship between GLP and QA. By replacing the term “laboratory” in the phrase “good laboratory practice” by an appropriate term, this schematic could apply to other elements of the environmental analysis process.

Environmental analysis studies benefit greatly by organizing QA on a very formal basis. Allocation of responsibilities should be clearly delineated, and reports should bear signatures. Each major study element should be described in a “Quality Assurance Plan”, should be detailed in a “Quality Assurance Manual”, and should be the responsibility of a “Quality Assurance Officer”. It is widely recognized that independent audits by impartial expert auditors offer a guarantee that GSP are maintained. An even stronger guarantee results when such independent audits are performed on behalf of an authoritative certifying organization, and methods are vetted against published standard protocols (e.g. ISO/IEC Guide 25) as part of a formal accreditation process. Basically accreditation is a formal recognition of the technical competence of an organization to carry out specific defined methodologies and to produce credible results.

2.2 International Standardization of Methodologies

There has been increasing recognition of the need for international adoption of harmonized standard methodologies to ensure data collected by different agencies are comparable. This is particularly important with regard to data sets collected to characterize transboundary and global environmental problems. ISO has been taking a lead role towards such international standardization, and has published a number of standard methodologies. In 1987 the ISO released ISO 9000, its first core series of standards for QA. The ISO 9000 series of standards addresses quality management and QA essentially with regard to any development, production, or service business, including analytical laboratories. Albu\(^{\text{(22)}}\) summarizes the implementation of ISO 9000 standards from the point of view of a company which had recently attained ISO accreditation. In 1996 ISO released the ISO 14000 series of standards, that specifically address environmental quality management, as summarized by Cicichnowicz.\(^{\text{(23)}}\) To date some 80 countries have adopted the ISO 9000 series as national standards. However, global implementation of these standards still remains to be accomplished. A major revision to the ISO 9000 standards is scheduled for release in 2000 or soon thereafter.
Harmonized technical protocols are being produced jointly by the ISO and other international scientific bodies such as the International Union of Pure and Applied Chemistry (IUPAC) and the Association of Official Analytical Chemists (AOAC) International. Horwitz has summarized the history to 1992 of the IUPAC/ISO/AOAC Harmonization Program. The ISO standards have had a major impact because of the associated rigorous certification process. Such certification is now firmly in place for analytical laboratories. Harmonized international standards and certification for other elements of the environmental analysis process have progressed more slowly. Sample collection is particularly lagging behind in this regard, and as a result is often viewed as the Achilles’ heel of the environmental analysis process.

With specific regard to laboratory accreditation, it should be pointed out that there is a common misunderstanding that registration to ISO 9000 automatically assures the validity of specific test results to a level equivalent to accreditation to ISO/IEC Guide 25. Both this guide and also EN 45001 (a laboratory guide well known in Europe) do assure validity of test data to an established technical competence. However, ISO 9000 does not as thoroughly address technical credibility and competence. (It is expected that the proposed new International Standard ISO/IEC 17025 will soon replace both ISO/IEC Guide 25 and EN 45001.)

3 QUALITY SYSTEM FOR THE ENVIRONMENTAL ANALYSIS PROCESS

Quality planning is absolutely essential if an environmental analysis program is to produce credible results. Therefore, senior management must ensure that quality planning is understood, implemented, and maintained at all levels of an organization. For environmental analysis programs, it is strongly preferred that organizations formally conduct their operations in accord with appropriate international standard protocols. Even where no such

format arrangements are in place, it is mandatory that GSP be employed on a rigorous basis. Each organization involved in the environmental analysis process must establish a “documented quality system” (DQS) for each and every function where controls are crucial to ensure the quality of the data. This DQS must be approved and endorsed by senior management, and must also be communicated to all staff. Typically there are three types of DQS documents:

- the “QA Manual”, which states the organization’s policies and commitments to quality, with emphasis upon commitments to national or international standards;
- the “QA Plan”, which details how the organization will meet and achieve the commitments of the QA Plan;
- standard operating protocols (SOPs), which are task-specific instructions for correct activity performance, and for quality criteria to be achieved.

(Note that some organizations use “QA Manual” with the above definition for “QA Plan” and vice versa; other organizations use one term to cover both; other organizations use quite different terms. Also, some organizations prefer to employ SOP as the acronym for standard operating procedures.) Every person participating in the environmental analysis process has responsibility to maintain a high standard of QA. Nonetheless, large organizations usually find it beneficial to assign one person primary responsibility to ensure that QA actually is maintained within an organization. This person usually is referred to as the “QA Officer.”

Environmental analysis programs can be divided into a number of discrete interlinked elements. Clark and Whittle(12) have suggested a 14-element model of such a linked multielement environmental analysis process. A schematic of this model is presented in Figure 2. This model divides the overall monitoring process into an ordered cyclical series of linked elements. For large environmental programs, each element (sometimes several adjacent elements) will be performed by different organizations, and therefore will have its own separate QA Manual, QA Plan and QA Officer. It is important that good communications be maintained between persons responsible for the various elements, so that effective and timely feedback can occur whenever problems occur. Large programs require central coordination of activities to ensure effective communication and overall-project management. Each element of the environmental analysis process is subject to changes and enhancements over time, reflecting improvements in instrumentation and methodology. The reliability of the information often is determined by the weakest link of the interlinked elements. In view of the rapid pace of technological change, tracking and characterizing the impacts of these changes on the collected data warrants a substantial QA effort. QA forms an integral part of each element of the environmental analysis process, as summarized in the following discussions.

3.1 Quality Assurance for Program Design

The ‘design element’ of environmental analysis programs defines the study boundaries, the specific study objectives, and the data collection strategies to meet those objectives. Every environmental analysis program should have specifically designed goals (in the QA Manual) and also effective strategies to meet those goals (in the QA Plan). Nonetheless, many environmental programs continue to be poorly designed and implemented, to the extent that the results compromise the intended objectives. Laane and ten Brink(12) and also Maher et al.(13) note that a poor standard of design and implementation of environmental surveys has resulted in massive collections of data which are “data rich but . . . information poor”. One strategy to ensure environmental analysis programs do produce data fit for their intended purpose, has been to specify that DQOs must be established at the design stage of the environmental analysis process. DQOs are derived from the intended use of the data, and serve as criteria for data acceptability, as is described by Keith. The primary QA goal for the design element of environmental analysis programs is to ensure environmental analysis programs do produce data fit for their intended purpose, has been to specify that DQOs must be established at the design stage of the environmental analysis process. DQOs are derived from the intended use of the data, and serve as criteria for data acceptability, as is described by Keith. Two examples DQOs are (a) that the analytical variance for each parameter should not exceed 4% of the observed local variance and (b) that the sum of the analytical variance plus sampling variance should not exceed 20% of the observed local variance. Both of these DQO rules have been employed in genuine circumstances, as described by Ramsey et al.(26) and Clark et al.(27) Such methods are cost effective, particularly when they permit one to weed out inappropriate methods which fail to produce useable data. The disadvantage of DQOs and of statistically valid sampling designs in general is that some environmental analysis programs may not be economically realistic, and the study manager must grapple with the choice of finding additional funds, designing a reduced-scale program, developing new methodologies, or collecting data that are of questionable merit.

The primary QA goal for the design element of environmental analysis is to ensure that specific study objectives are defined, and appropriate data collection strategies are implemented. Comprehensive consideration of the statistical aspects of program design is a priority. Fortunately, there is a sizable literature on this topic, e.g. Rose and Smith. Comprehensive consideration of the chemical aspects of program design is equally a priority. Quantitative understanding of the chemistry of ecosystems
involves both thermodynamics and kinetics. Equilibrium approaches are useful in understanding the inorganic composition and reactions in simple aqueous ecosystems. However, as detailed by Brezonik in an excellent textbook, kinetic approaches are essential when it comes to understanding the composition and reactions within environments where nonequilibrium conditions persist. An advantage of the cyclic model of environmental analysis is that study objectives, study area boundaries, DQOs, and sampling strategies can be optimized as new information comes available each cycle.

3.2 Quality Assurance for the Study Plan

The “study plan” is a DQS document which details the responsibilities, schedule, and budget of every participant on an environmental analysis project. This plan defines the tasks and steps necessary to attain each goal or objective specified in the design. The QA aspect of the study plan should ensure that all participants are familiar with the plan, that each participant has clearly defined responsibilities, and that there is effective communication between study participants. Any deviations from budgets and schedules should be identified and rectified on a timely basis. Evaluation of historical data (for either the study ecosystems or for similar ecosystems), pilot studies, and mock projects using surrogate data all assist in early identification of conflicts between study participants with regard to objectives, responsibilities, schedules, or methods. These practice studies also serve to identify training requirements, and equipment or methodology deficiencies.

3.3 Quality Assurance for Protocols

The “study protocols” (variously called “standard operating protocols”, “standard operating procedures”, “SOPs”, or “work instructions”) are formal written procedures for all methods employed during the course of an environmental analysis study. Included in the SOPs are details of records to be maintained, QA activities, and remedial responses to be employed in response to various types of method failure. The SOPs should specify the reporting and evaluation of QA results on a regular and timely basis, and should also specify acceptance criteria for specific QA programs. The QA aspect of study protocols must ensure that these protocols are kept up-to-date and are readily available to all members of the study team, that they do genuinely reflect actual practice, and that a copy of the protocols is safely maintained in some permanent archive. In spite of the best of intentions to use only the most trustworthy instruments and most up-to-date methods, sometimes this is not possible. Instrument failure, accident or illness, or other unexpected events may necessitate the use of nonstandard practice. Therefore, provision must be made within the protocols for handling contingencies and deviations from normal practices.

3.4 Quality Assurance for Presampling Preparation

“Presampling preparation” includes those activities that take place prior to traveling to the sampling locations. These activities include preparation of reagents and sample bottles, maintenance and calibration of equipment, and shipping of materials to remote locations. The QA for presampling preparation include ensuring that maintenance and calibration activities are performed correctly, on schedule, according to SOP specifications, and also that appropriate maintenance and calibration records are kept. It is particularly important that reagents, reagent water, and sample bottles be checked for contamination. If material is being shipped to remote locations, late or incomplete shipments can result in significant program interruption. Checklists are particularly useful at this stage of the environmental analysis process. Table 3 is based upon a checklist published by Keith.

3.5 Quality Assurance for Training and Liaison

“Training and liaison” covers both training programs plus communication between headquarters staff and field personnel. Staff training should be ongoing, and particularly should be emphasized where changes in personnel are frequent. Associated QA includes verification that training records are maintained and up-to-date, plus verification that personnel assigned specific tasks have the necessary education, training, and experience. Safety training is essential for everyone, even the most senior staff.

For those environmental analysis programs that have separate headquarters staff and field staff, effective two-way communication is important. Information regarding problems, unusual events, and deviations from standard practices must be communicated rapidly between study participants, in order to avoid misunderstandings and continued use of flawed methods, or inappropriate use of flawed data. Associated QA includes verification that communication records are complete and up-to-date, and verification that personnel are familiar with protocols for handling contingencies and deviations from normal practices.

3.6 Quality Assurance for Sample Collection

The “sample collection” element of the environmental analysis process includes those activities which take place immediately preceding and during the collection of samples. These activities include on-site maintenance and calibration of equipment, site selection, sample collection, on-site sample handling, in-situ measurements, photography and all related observations, measurements,
and records. Photographs and detailed field records are invaluable during data interpretation. For the environmental samples to be representative of the ecosystem, spatial and temporal gradients should be sampled adequately to characterize the gradients. Sharp gradients are best avoided if practical, since they require very intensive monitoring effort to be characterized. A selection of papers from the large literature on this topic includes Kramer, Stroomberg et al., Wagner, and Barcelona. Heterogeneity at a site is usually explored by collection of multiple samples. QA aspects of the sample collection should ensure that SOPs are followed, details as to site location and condition are recorded, and details as to sample collection and sample characteristics also are recorded. Proactive QA should include specific protocols to confirm that samples are representative of the ecosystems being studied, that samples have not been contaminated through the sampling process or otherwise modified, and that each sample has been properly and uniquely identified. Since ecosystems are both heterogeneous and dynamic, any collected samples also will be both heterogeneous and dynamic. This fact has major consequences for the QA aspects of any environmental analysis program. Highly dynamic variables must be either preserved or measured in situ or on-site. Those ecosystems that are highly heterogeneous over time or space require intensive sampling effort in order to be adequately characterized. It is often worthwhile to employ on-site measurements of a few variables in order to target effective sample collection from such heterogeneous ecosystems (these samples subsequently being analyzed under laboratory conditions for the entire suite of relevant contaminants). With regard to collection of samples for trace and ultratrace analytes, contamination is difficult to avoid. Therefore, scrupulous care and intensive QA are required, such as that suggested by Stewart and Anderson for metals. Proactive QA should include intensive use of blank samples, replicate samples and other QA/QC samples. Table 4, based on Cavanagh et al., tabulates common QA/QC sample types along with brief descriptions as to the purpose of each type. Note that replicate samples should be collected as closely located in space and time as possible. Preferably a multiple sampling device should be used to collect simultaneous, immediately adjacent replicate samples. GSP call for some proportion of QA samples to be submitted on a blind basis. GSP also call for independent audits of sampling. Additionally, where two study teams are carrying out environmental analysis studies having overlapping or adjacent study boundaries, simultaneous independent sampling at a common site by the two sampling teams is encouraged.

3.7 Quality Assurance for Sample Handling
The “sample handling” element of environmental analysis includes all activities which occur between collection

LOD, limit of detection.
of a sample and receipt of that sample at a scientific institution or laboratory responsible for cataloguing, warehousing, or analysis of the sample. Included in the sample handling activities are sample preservation, sample packaging, and sample transportation. The QA aspect of sample handling includes those activities to assure sample integrity. Proactive QA should include protocols to establish that unstable samples are stabilized and handled appropriately, and also to assure that samples are not contaminated through the sample handling activities. GSP call for the stability of analyte to be confirmed for each type of sample being studied. Note that some analytes will degrade even if deep-frozen. Rate-determining factors for sample degradation usually include the rates of hydrolysis, of photolysis, and of oxidation.

Poor technique with regard to sample handling will produce unrepresentative samples and contribute to uncertainty of data. Contamination of sample may come from use of improperly cleaned containers, dirty container caps, dirty or inappropriate sampling equipment or filtration equipment, contaminated preservatives, cross-contamination between samples, exposure of samples to air, and loosely capped containers. GSP call for strict attention to appropriate SOPs both to avoid contamination, plus intensive in-house QC studies to identify contamination should it occur.

### 3.8 Quality Assurance for Laboratory Analyses

“Laboratory analysis” activities encompass all activities from receipt of samples at the laboratory doors to issuance of analysis results either in a signed laboratory report or in electronic form. Every laboratory activity must have an associated QA activity. Comprehensive specifications for all laboratory QA/QC must be detailed in the DQS documents, i.e. the Quality Manual, Quality Procedures and Work Instructions or SOPs. The laboratory must implement internal quality audits to verify the effectiveness of the quality system. Internal quality audits should be carried out by personnel (e.g. the QA Officer) independent of those having direct responsibility for the activity being audited. The results of internal quality audits must form an integral part of the input to management review activities.

The primary objectives of QA/QC are to ensure that unstable samples are either stabilized or analyzed expeditiously, to ensure that heterogeneous samples are either homogenized or properly subsampled, to ensure that samples are not contaminated through the subsampling and analytical processes, to ensure that the results of analyses are both consistent and comparable to those from other laboratories, and to ensure that GLP are followed. Both sample degradation and sample contamination are controlled by strict adherence to published SOPs, accompanied by regular in-house studies designed to identify such problems. These in-house studies typically include both routine analyses of sample blanks and reference materials within each batch of analytical test samples, plus replicate analyses of a regular proportion of samples. Such a QC program is often referred to as “batch-specific QC”, or as “batch QC”. The choice of samples for reanalysis should be randomized, unless the analyses are automated, in which case the replication may be a fixed interval (e.g. every 10th test).

Every laboratory should have general benchmark limits or DQOs that must be met for each variable. These DQOs pertain to the key operating characteristics of analytical methods, including:

• trueness (or bias)
• precision (repeatability and reproducibility)
• detection limit
• sensitivity
• selectivity
• measurement range.

(Readers are cautioned that terms such as “accuracy”, “reproducibility”, and “repeatability” have been used with very different meanings by different schools of analytical chemistry.) These characteristics sometimes are referred to as “figures of merit”, since they form the basis for evaluating whether or not particular methods are appropriate for some specific purpose. As one example of a DQO, Richardson and Morrison(32) reported that their laboratory has an expectation that “over a 5-year period, precision and trueness will not exceed ±10% (2σ) for a given element when that element’s concentration is more than 10 times the detection limit” of the method in question. Solsky(33) noted that selective exclusion of data to achieve such DQO goals is fraudulent. Laboratory results are proven to be comparable to those provided by other laboratories via analyses of certified reference materials (CRMs) and through participation in interlaboratory proficiency studies. GSP for laboratories is usually referred to as GLP. GLP is usually verified by independent audit, often associated with an ISO-based certification process. The flowchart in Figure 3, from Agemian,(17) shows the relationship between GLP and QA.

The laboratory that performed the sample analyses must carry out final inspection and validation of the test results in accordance with the Quality Plan, or as documented in the Quality Manual, in order to complete the evidence of conformation of the test results to laboratory-specified DQOs. No test results should be dispatched until all activities specified in the documented procedures have been satisfactorily completed and the associated QC data are available and authorized. Before release of data, statistical evaluation must indicate conformance of test data with regard to all essential elements of laboratory DQOs. Written reports must identify (usually by signature) the inspection authority (usually the QA Officer or Laboratory Manager) responsible for the release of the results.

3.9 Quality Assurance for Data Transmission

Once a laboratory has completed the chemical analysis of a sample, the results are transmitted to a client, either by paper report or by electronic transfer to a computer database. “Data transmission” includes all those operations and activities of the laboratory reporting process and of the client data entry process. The associated QA protocols ensure that a permanent record is kept of algorithms and procedures used to check, flag, calculate, validate, censor, or otherwise manipulate the results. The QA protocols also ensure that every sample is correctly identified, that all requisitioned tests had results reported, that analyzing laboratory and analyzing methods are unambiguously identified, that any changes and corrections to the data are formally documented, and that all results are backed up at some secure location to avoid data loss on event of fire or earthquake. Data residing on computer databases should be regularly audited to confirm data integrity and data authenticity. Worthington et al.(34) have published a summary of audit requirements for environmental data systems. Their paper includes both a checklist and recommended plans for corrective action.

Data assessment is an important subelement of the data transmission process. Each result is individually assessed against the DQOs. Values which meet these DQOs are accepted, values which are marginally outside the DQOs are accepted with some appropriate qualifier or flag, and values which are severely fail the DQOs are rejected. Figure 4 presents a guidance flowchart for data assessment. After the data assessment process, data usually are flagged with single-character qualifier codes to indicate the data quality. Since currently there is no consistency among various agencies in the use of such qualifier codes, reports including such codes should clearly define any qualifier codes employed. Several example sets of data quality codes are given in Table 5.

GSP call for analytical results to be reported uncensored and with unambiguous estimate of analytical error. Nonetheless, many laboratories prefer to report data which are both left-censored and without any accompanying statement of analytical precision. Fyles et al.(37) have published a detailed overview of this problem. They reported that a recent survey of environmental laboratories in Canada, Europe, and the Pacific Northwest United States found that both digit truncation (i.e. rounding or simple truncation of numerical values) and distributional truncation (i.e. replacement of a numerical value by text such as “nd” for “not detected”) is nearly universally practised. Fyles et al.(37) also demonstrated how both types of truncation genuinely do result in loss of information. Horwitz(38) noted that both random and nonrandom components of laboratory uncertainty should be reported, and explained why chemists are loathe to do this because of the very large magnitude of uncertainty for trace and ultratrace analyses. Byralsen et al.(39) suggested that the uncertainty for a measurement cannot be determined with a degree of scientific objectivity equivalent to that for the measurement itself. The arguments in the literature both for and against left-censoring have been summarized by Clark and Whitfield,(19) Porter et al.(10) called for reporting of measurement precision, and also listed other papers making similar recommendations. Even when laboratories do report analytical precision,
various algorithms are employed. Therefore, it is important that laboratories should unambiguously define the precision algorithm used. Currently the 95% CI appears to be gaining support to become the standard algorithm to be employed for expression of precision. (Personally the author favors the 95% nonparametric CI, but that is not a popular choice).

Each method of chemical analysis has a range of concentrations for which it can produce reliable results for a specific chemical matrix. By IUPAC definition, this is known as the “region of quantitation” and is bracketed by the “limit of quantitation” (LOQ) and the “upper limit of quantitation” (ULOQ), as described in Figure 5. A continuing problem with regard to data transmission is how to cope with results that fall below the LOQ. Many laboratories define a detection limit or “LOD” and report data above the LOD as if quantitative. Both LOD and LOQ are based upon $\sigma$, and thus are directly related to reliable estimation of measurement uncertainty. The term “method detection limit” (MDL) is synonymous with LOD. For results below the LOD some laboratories transform the values to a text entry such as “nd” (for “not detected”). Other laboratories revise the observed result to the LOD and set an appropriate data qualifier flag. Still other laboratories report down to the lowest increment reading on the analytical instrument and flag values either “T” below the “criterion of detection” (see Table 5 for definition), or “W” below the lowest increment reading. Many laboratories prefer to transform or to flag results below the LOD in order to emphasize their lack of confidence in the numeric results. However, as summarized by Clark and Whitfield(19) and Fyles et al.(37) such “left-censoring” does result in information loss and inconvenience. When censored data must be discarded as unusable, the effort expended to collect and analyze those samples has been wasted. For situations where censored data are usable, there still is some wasted effort, since many additional samples are required to reach statistically meaningful decisions. (Moreover, where analytical chemistry fails to provide estimates of the concentrations of target elements or compounds, risk assessors will turn to more dubious sources of information such as economic production or disappearance data, with worst-case scenarios.) GSP call for all analyses to yield results that primarily fall within the region of quantitation. Therefore, an analytical method preferably should only be employed if the estimated LOQ falls well below the lowest expected experimental value or regulatory criterion. Where inappropriate methods are employed, GSP call for the results to be unambiguously identified as suspect.

3.10 Quality Assurance for Data Validation

The “data validation” element of environmental analysis includes validation checks of accumulated data sets to confirm that DQOs have been achieved. It also includes validation checks of field and laboratory QA/QC results associated with those accumulated data sets. Data validation confirms that data sets are accurate, complete, and defensible for the intended use. The DQS component of data validation should specify what methods and
Figure 5 Schematic presenting IUPAC-style detection limit definitions. (Reproduced with permission of the American Water Resources Association from M.J.R. Clark, P.H. Whitfield, ‘Conflicting Perspectives About Detection Limits and About the Censoring of Environmental Data’, Water Resour. Bull., 30(6), 1063–1079 (1994).)

checks are to be employed to check the data, what DQOs employed, and what remedial actions to be taken when data fail validation. The characteristics of the data sets evaluated usually should include precision, trueness, representativeness, completeness and interlaboratory comparability. It is preferable that all data results should be fully validated. Where all results are not fully validated, it is important that the degree of validation be clearly indicated. Currently no standard set of validation codes has been established. Three example sets of validation codes are given in Table 6. Note that (a) data inspection and validation by a laboratory’s QC process are required before results are released, (b) data assessment of individual results is required before data are added to a computer database, and (c) data validation of data sets (multiple results) is required prior to use and interpretation of the data sets. It is particularly important to note that these are three independent processes. The fact that one of them was performed is never an excuse for either of the other two to be omitted.

### 3.11 Quality Assurance for Data Approval

“Data approval” refers to the process by which an agency gives formal acceptance to data, prior to their release to other organizations or to the public. Often the terms “validated” and “preliminary” are used to distinguish between data that have been officially approved for release and that are believed to be credible, and data that have not been officially released and that may or may not be credible. Senior management (i.e. having executive responsibility) must ensure that the Quality Plan for the overall environmental analysis process documents procedures for the inspection, validation, and approval of test data in order to ensure that the specified requirements in the DQOs are met. Records of validation must be kept. Where data fail to meet DQOs, the procedures for control of nonconforming data shall apply. This might include rejection of results, or acceptance with a warning flag. If preliminary data are released to other parties or to the public, the definition of the term “preliminary” and the implications for data quality and data interpretations must be clearly defined for the benefit of the data recipients.

### 3.12 Quality Assurance for Data Provision

The “data provision” element covers the release and distribution of environmental data sets, whether to the public, to university scientists, to commercial business, or
to government agencies. The QA associated with data provision should ensure that the results are perceived by all parties to be complete, accurate, believable, timely, and understandable. There is increasing recognition of the necessity for comprehensive and efficient mechanisms to report both the data results of environmental analyses, plus also the judgmental information as to the quality and usability of data. Pink et al. reported the development of an approach which includes assessing, documenting, and reporting what is known about the data quality and consequently the usability of data. Their approach integrates field data, analytical results, QC data, and historical data. As the world moves more and more to electronic (“high-tech”) paperless exchange of information, QA must include provision for the security of the integrity of data sets.

3.13 Quality Assurance for Statistical Analyses

“Statistical analyses” of environmental analysis data range from simple hypothesis testing methods to sophisticated time-series analyses and forecasting techniques. Before statistical evaluations commence, targeted data sets should be examined for reliability caution flags, lack of completeness, anomalous values, left-censoring, data truncation, nonhomogeneous variance, pseudo-replication, autocorrelation, serial correlation, and non-normal distribution of random error – all these problems being commonplace for environmental data sets. Long-term environmental analysis data sets must also be examined for artifacts introduced by changes in frequency or timing of sample collection, and by changes in sampling methods or in analytical methods. In addition, the sampling uncertainty, the analytical uncertainty, and the total assay uncertainty must all meet the study DQOs and be significantly smaller than the local environmental uncertainty. Ideally both the statistical techniques to be employed and also the responses to each of the aforementioned problems should be predefined in a series of study DQOs developed (with the assistance of a qualified statistician) prior to initiation of the project. Clark and Whitfield and Fyles et al. have summarized the literature regarding statistical methods to cope with the commonly encountered problem of left-censoring.

GSP call for correct statistical methods to be effectively applied. However, Millard reported that there is widespread misuse of statistics in environmental monitoring applications. Millard attributed this problem to a general failure of environmental agencies to hire professional statisticians. (Millard additionally expressed concern that the widespread availability of statistical packages for personal computers and the growing trend towards expert systems seem likely to exacerbate this problem.) For hypothesis testing, GSP call for $\alpha$ to be always reported, and also specifically call for $\beta$ to be reported whenever a statistical analysis does not reject a null hypothesis ($\alpha$ is the probability of type I error, the rejection of a true null hypothesis; $\beta$ is the probability of type II error, the failing to reject a false null hypothesis). Peterman reported in 1990 that some 98% of the papers he had surveyed in fisheries and aquatic sciences had failed to report $\beta$ whenever a null hypothesis had not been rejected. Peterman also reported that 52% of papers

As the world moves more and more to electronic (“high-tech”) paperless exchange of information, QA must include provision for the security of the integrity of data sets.

3.13 Quality Assurance for Statistical Analyses

“Statistical analyses” of environmental analysis data range from simple hypothesis testing methods to sophisticated time-series analyses and forecasting techniques. Before statistical evaluations commence, targeted data sets should be examined for reliability caution flags, lack of completeness, anomalous values, left-censoring, data truncation, nonhomogeneous variance, pseudo-replication, autocorrelation, serial correlation, and non-normal distribution of random error – all these problems being commonplace for environmental data sets. Long-term environmental analysis data sets must also be examined for artifacts introduced by changes in frequency or timing of sample collection, and by changes in
he surveyed had incorrectly drawn conclusions for those situations as if the null hypothesis had been proven to be true. To ensure that appropriate statistical procedures are employed to cope with the statistical aspects of environmental analysis, independent audit by a professional statistician is strongly advised.

### 3.14 Quality Assurance for Reporting

Decision makers prefer reports which are concise, which make explicit recommendations, and which clearly identify important variables. Also, as noted by Cullen,\(^{(45)}\) it is important to appreciate that conflicting advice from otherwise credible sources tends to be disregarded. While it is important that scientists understand the fine details comprising an environmental analysis, many of the people who encounter the published reports will be nonscientists. Therefore, summary-type explanations should be emphasized. Conversely, scientists reading the reports will want the detail, preferably in machine-readable form. Short interpretive reports accompanied by separate technical appendices can be both effective and cost efficient.

QA for the reporting element of environmental analysis has five main objectives:

1. to ensure that the overall environmental analysis program from start to finish is credible;
2. to ensure that the reporting presentation is relevant to known environmental problems and pending resources management decisions;
3. to ensure that the findings are issued on a timely basis;
4. to ensure that the interpretive reports are understandable to nonscientists; and
5. to ensure that total assay results and associated QA/QC results are available to other scientists and secured on a permanent archive.

### 4 ERROR CONTROL

All scientific measurements are subject to error. The goal of “good measurement practice” is to minimize errors sufficiently that they do not adversely affect resource management decisions. Samples collected from some particular population in any particular ecosystem must be so chosen, so collected, so preserved, so analyzed, so reported, and so interpreted such that the results do truly and accurately represent the entire population being characterized. Wagner\(^{(16)}\) discussed this topic in some detail, and emphasized that “The main problem for QA in environmental sampling is how to guarantee biological, ecological and geographical representativeness of the samples”.

As indicated in Figure 6, there are many sources from which errors may arise during the environmental analysis process. The nomenclature of errors usually refers either to the general source of the errors or to the character of the errors. Where discrete samples are not taken, usually the errors are simply referred to as “measurement errors”. If discrete samples are collected and subsequently taken elsewhere for analysis, “sampling errors” are those errors which arise from the instant of sampling until the instant the laboratory takes receipt of the sample. “Analysis errors” are those errors which arise after the instant a sample arrives at the laboratory. “Total assay error” is the sum of sampling error and analysis error, as discussed by Clark et al.\(^{(27)}\)

With regard to the character of errors, there are three general categories of error. These are “random errors”, “nonrandom errors”, and “gross errors”. Wagner\(^{(16)}\) has published a useful summary of error characteristics, quality, and magnitude, although using a slightly different nomenclature to that employed here. Wagner’s summary is reproduced in Table 7. It should be noted that the term “uncertainty” is often employed as synonymous to “error”.

#### 4.1 Random Errors

Even the most carefully performed measurements are subject to small irregular random errors. When the random error results from numerous sources of small errors, it is reasonable to assume (because of the central limit theorem) that the distribution of random error is normal. The assumption that errors are primarily random in nature forms the essential foundation of modern quantitative statistics. This assumption is also fundamental to the techniques described by Ramsey et al.\(^{(26)}\) and Clark et al.\(^{(27)}\) for determining the relative proportions of analytical error, sampling error, and local environmental heterogeneity by variable within environmental analysis data sets. Those data sets influenced primarily by random error (i.e. minimally influenced by nonrandom error) are usually described as being “in control” or “in statistical control”.

It is important to appreciate that an analytical method may not yield usable results even when that analytical procedure is fully under control with no gross errors, no observable nonrandom error, and minimal random error. For example, an environmental analysis DQO for some specific purpose might set a precision limit at ±10% for all analytes. However, according to Cantillo and Lauenstein,\(^{(44)}\) laboratories typically set limits of precision DQOs for trace organic control substances at ±30% on average for all analytes and ±35% for
Figure 6 Multiple sources of total assay error. For discrete samples, “sampling errors” are those errors which arise from the instant of sampling until arrival of the sample at a laboratory. “Analysis errors” are those errors which arise after the instant a sample arrives at a laboratory. (Reproduced with permission of the American Water Resources Association from M.J.R. Clark, P.H. Whitfield, ‘Conflicting Perspectives About Detection Limits and About the Censoring of Environmental Data’, Water Resour. Bull., 30(6), 1063–1079 (1994).)

4.2 Nonrandom Errors

Nonrandom errors are not random and usually are not normally distributed. As a class they confound statistical analysis. Therefore, an important role of QA is to recognize and to remedy any occurrence of nonrandom error. There are five important types of nonrandom

individual analytes. These data would be unsuitable for the intended purpose even though fully in control. This problem of finding suitable analytical methods becomes more difficult for ultratrace analyses. From retrospective investigation of a number of interlaboratory proficiency studies, Horwitz et al. have determined that the interlaboratory precision expressed as coefficient of variation (CV) is an inverse function of concentration expressed on a mass/mass basis, as illustrated in Figure 7. In other words, the lower the concentration of analyte in a given chemical matrix, the greater is the random uncertainty of analytical results.
Table 7  Characteristics, quality and magnitude of errors categorized by different elements of environmental analysis monitoring.
(Note that the nomenclature used in this table is slightly different from that employed in the main article and also that the table was modified slightly from the original for clarity. <sup>a</sup> “Absolute error” is the sum of absolute deviations from a target value divided by the number of measurements.

<sup>b</sup> The term “factor 2/2” indicates that the true result is between 1/2 and 2 times the reported value.

error commonly encountered for environmental analysis. The first type is very similar to random error in that the overall error is the sum of small errors from many different sources. However, one or more of the nonrandom sources of error are of sufficient magnitude so that the overall error distribution is not normal. This situation is best identified by testing error distributions for normality. Appropriate distribution-free (sometimes called nonparametric) statistics often can cope with this situation. (Random error may appear to be non-normal if transformed or collected in inappropriate units; transformation will return the data distribution to normal but cannot rectify nonnormal error. Distribution-free statistics is preferable to transformation if there is doubt as to whether the data distribution is truly or apparently non-normal.) The second type of nonrandom error is referred to as “systematic error” because it shows some reproducible pattern. This type of random error is usually recognized through use of CRMs, from results of interlaboratory proficiency studies, or from comparisons of independent methods of analysis. Where the systematic error is highly reproducible, it may be possible to correct it by either calculation or instrumentation. This is the basis of blank correction. A third type of nonrandom error occurs as infrequent transient events where the error is of similar magnitude to the measurement being taken. This type of error is recognized through the use of statistical outlier tests. A fourth type of nonrandom error (“persistent nonrandom error”) both occurs frequently in a data set and is of similar magnitude to the measurements themselves. Like systematic error, this type of random error is usually recognized through use either of CRMs or of independent methods of analysis. Data sets containing persistent nonrandom error are not in statistical control and are best discarded, with more appropriate assay methods being used thereafter. Data sets having a majority of results below the LOQ are particularly vulnerable to persistent nonrandom error. This type of error also occurs for data
sets based on methods that are susceptible to interference or that are inadequately selective to the analyte of interest. A fifth type of nonrandom error has periods of random error intermixed with periods of persistent nonrandom error. This often occurs for situations where one or more series of measurements above the LOQ are intermixed with series of measurements below the LOQ. It may be possible to segregate the trustworthy from the nontrustworthy results in such situations.

In classical stoichiometric chemistry (concentrations >0.1%), systematic error is viewed as the predominating type of nonrandom error, and also is viewed as being generally correctable. Much of the literature on stoichiometric chemistry treats the term “systematic error” as synonymous with “nonrandom error”. Analytical error was viewed as being composed of a random error component plus a systematic component or bias, and the bias could be estimated and subtracted. It must be emphasized that the simple model of errors employed for classical stoichiometric chemistry is inappropriate for modern trace analysis (concentrations < 0.1%). Although the five types of nonrandom error offer a convenient classification model for trace analyses, often it is not possible to classify the source of discrepancies in environmental analysis results. Often different sources of error are confounded with each other.

A question that often arises during discussion of errors is whether or not statistical outliers should be removed from data sets. GSP permit the removal of statistical outliers only if anomalous experimental conditions can be documented. Removal of statistical outliers without proof of anomaly is controversial, but Grant et al. argued that the removal of single aberrant values can be justified. Multiple outliers are frequently encountered in environmental analysis, and often there is considerable incentive to remove multiple outliers without proof of anomaly, since leaving outliers in data sets distorts the latter, and tracing their origin is a never-ending, expensive task. Nonetheless, it is preferable to leave unexplained outliers within data sets, and to address this problem both with a reasonable (i.e., affordable) effort to trace their cause, and through the use of statistical procedures that are robust to the presence of outliers. In this regard, it should be noted that outliers have a considerable impact on statistical parameters such as mean and standard deviation, but little impact upon statistical parameters such as the median or the inner quartile range (range from 25th to 75th percentiles).

Samples that truly do not contain any analyte of interest but which are reported to contain the analyte are called “false positives”. Samples that do truly contain the analyte of interest but are reported to have no analyte present are called “false negatives”. It should be appreciated that the detection limit model always permits some false positive and false negative values. However, the proportion of false positives and false negatives should be that permitted by chance alone. If nonrandom error predominates over random error (as it well might near the detection limit, or for sample matrices which differ substantially from the matrix of the calibration samples), then the occurrence of false positives and false negatives is not controlled. For such a situation it is even possible for a majority of observed results to be false positives or false negatives. Interpretation of such untrustworthy data sets can yield misleading conclusions.

4.3 Gross Errors

Gross errors result from accidents, equipment malfunction, or human blunders. These errors are of large magnitude, and will greatly distort data interpretations if not identified. An amusing element of gross outliers is the great variety of names assigned to this type of error by various authors, e.g. blunders, catastrophic errors, flagrant outliers, fliers, gross errors, lurking outliers, obviouous blunders, outlandish results, outrageous outliers, and rogue values. Fortunately, the large size of these errors often makes them easy to spot. These errors particularly stand out from routine results on graphic plots. They may also be identified as statistical outliers by appropriate statistical tests. The most confusing type of gross error stems from simple misidentification of samples. It must be emphasized that even the most careful program is vulnerable to gross errors, and one should never give in to the temptation to relax QA programs to economize. Unidentified gross outliers can so greatly distort data as to render them meaningless.

5 DETECTION LIMITS AND LIMITS OF QUANTITATION

5.1 The International Union of Pure and Applied Chemistry Detection Limit Model

GSP call for all environmental samples to be analyzed by analytical methods that have a definite relationship (often but not always linear) between observed and true values, and that also have analytical error that is minimal, homogeneous, and random. Most analytical procedures specify a concentration range for which such a definite relationship has been established, within allowances for analytical error. For measurements made outside this concentration range, the relationship between “true” and observed concentrations of analyte can become nonlinear. Both random and nonrandom analytical errors can grow rapidly larger with increasing distance from the linear range. However, with the growing importance of trace and ultratrace analyses of environmentally significant
contaminants, a number of analyses are now performed at concentrations substantially below the lower extreme of the quantitative range. The literature contains numerous procedures, definitions, and algorithms for determining analytical boundaries (detection limits and quantitation limits) to distinguish between data that are meaningful, somewhat meaningful, and not meaningful. A 1990 review by Oresic and Grdinic(47) on this topic included over 500 citations.

As discussed by Long and Winefordner, IUPAC has issued a standard set of definitions regarding detection limits. Figure 5 presents a schematic representation of a detection limit model that conforms to definitions endorsed by IUPAC. For this model, the most reliable quantitative data fall in the “region of quantitation”. The lower boundary of this region is called the “LOD”. Below the LOQ boundary, there is a range of concentrations called the “region of detection” for which there is a high probability that samples genuinely containing the analyte of interest can be distinguished from samples (called “sample blanks”) of similar matrix which genuinely do not contain the analyte of interest. The lower boundary of the region of detection is called the “LOD” (one often hears this boundary referred to as the “detection limit”). Below the LOD, the probability of distinguishing between samples which genuinely contain analyte and sample blanks falls rapidly with decreasing concentration. That concentration below which test samples and sample blanks cannot be distinguished is called the “criterion of detection”. There are a number of flaws in the detection limit concept, as discussed by Kurtz et al. and Clark and Whitfield. Not the least of these is the fact that a number of laboratories do not precisely follow the IUPAC approach, even though they may use similar nomenclature. The detection limit concept as correctly applied offers a useful tool towards choosing analytical methods appropriate to the objectives for programs of environmental analysis. The Kurtz et al. paper includes advice from a panel of scientists on how data at or near the detection limit should be produced and reported. Their paper includes four real-world examples, and particularly advises that reported results at or near the detection limit should have statistical support.

The detection limit concept was developed for the specific intention of comparing analytical instruments and methodologies. Estimated LODs and LOQs are only meaningful for interference-free conditions. Clark and Whitfield advised that results below the LOQ should not be assumed to be in statistical control. GSP call for such assumptions to be proven. This is particularly important when test samples have greatly different chemical composition (matrix) than the calibration samples. To avoid problems with regard to nonrandom error (including false positives and false negatives), all experimental analyses should fall well above the LOQ. Many protocols define the LOQ as some simple multiple (usually a multiple of 3 or 10) times the LOD. Winefordner and Rutledge even suggested that a method should only be considered for application if the calculated detection limit is at least 100 times below the lowest experimental values expected.

5.2 Calculation of the Limit of Detection

Above the LOD, there is a statistical probability that samples that genuinely contain a specific analyte can be distinguished from samples that do not contain that analyte. When reaching such a statistical decision, there are two “errors of decision” which must be considered. For a type I decision error, one would have decided that there was analyte present in a sample when in fact that sample contained no analyte. For a type II decision error, one would have decided that there was no analyte present in a sample, when in fact the analyte was present. Depending upon the use of the results, sometimes one decision error is much more important than the other, and only the single important decision error is statistically tested. For other purposes both decision errors are equally important and both decision errors are tested.

If one assumes that analytical error is random, normal in distribution, and identical for test samples and blanks at the LOD concentration, then fairly straightforward decision rules can be established to ascertain the LOD. For example, if one repeatedly analyses a very low concentration of analyte in a specific sample matrix, and if one is willing to accept a 5% chance of a type I decision error and uncontrolled type II decision error, then the LOD will be 1.65 times the standard deviation of these results for a large number (>30) of analyses (Equation 1):

\[ \text{LOD} = 1.65s \] (1)

(This is because for a normal distribution 95% of the area falls below the mean plus 1.65\(s\) and 5% falls above that limit. The population standard deviation, \(\sigma\), is represented by the sample standard deviation, \(s\).) For a small number of analyses the LOD should be based on the \(t\)-distribution (Equation 2):

\[ \text{LOD} = t_{0.95} \frac{s}{\sqrt{n}} \] (2)

If one wished neither type I decision error nor type II decision error to exceed 5%, then for the same circumstances, the LOD would be estimated from Equation (3) for a large number of analyses or from Equation (4) for a small number of analyses:

\[ \text{LOD} = 3.29s \] (3)

\[ \text{LOD} = 2t_{0.95} \] (4)
5.3 Different Types of Limits of Detection

There are a number of particulars that substantially impact the final estimate of LODs and must therefore be detailed in SOPs and publications. First, is the LOD for an instrument exclusive of sample preparation and pretreatment? Or is the LOD for the entire method including all digestions, extractions, and other preparation steps? Or does the LOD include some but not all of the sample preparation and pretreatment steps? Second, what are the analyte concentrations and characteristics of the test matrix used to determine the LOD? The four usual preferences are deionized water, deionized water spiked with low concentrations of the target analyte, test samples having very low concentrations of target analyte, or test samples spiked with low concentrations of analyte. Third, are both type I and type II errors to be equivalently controlled, is one to be more greatly controlled than the other, or is only one to be controlled? Fourth, over what time frame were the test samples analyzed—all in one day would give a rather overoptimistic estimate of LOD.

The two most common strategies are either analysis of multiple sets of replicate aliquots over several weeks or analysis of a large number of duplicate samples over many months. Finally, were the analyses performed by more than one instrument, more than one technician, more than one laboratory? All this information has substantial impact on the results, and therefore must be specified in the laboratory SOPs and permanent archive records.

As noted previously, false positives can occur by random chance alone for a concentration near or below the detection limit. Also, nonrandom error is usually difficult to control at these low concentrations. This usually increases the number of false positives. The problem of false positives is of particular concern to agencies dealing with potent carcinogens or toxicants, where even a single false positive might cause undue public alarm. For these situations, some agencies and laboratories arbitrarily adjust the detection limit upwards to what is often called a “practical detection limit” (PDL). A similar strategy is sometimes taken to resolve difficulties with merging data from different laboratories having different LODs. The PDL strategy does substantially increase information loss through left-censoring. For merged data of different LODs, the worse information loss paradoxically is for the best (most sensitive) methods.

6 ASSOCIATED TOPICS

6.1 Quality Assurance Requirements of Legal Samples

Some samples are collected with the intent that the results will be used in a court of law, whether to enforce government regulations or for the purpose of other litigation. Such “legal samples” require rigorous adherence to protocols additional to those required for routine environmental monitoring. Both persons who collect the samples and persons who analyze the samples must be able to document appropriate training for duties performed with regard to the samples, and must be able to document and testify that the appropriate technical protocols were rigorously followed. These persons must also be able to testify as to results of the QA/QC programs associated with the legal samples. They also must be able to prove that neither sample containers nor reagents employed could have contaminated the samples.

Both persons who collected the samples and those who analyzed the samples must be able to establish, without doubt, that the samples are correctly identified and could not possibly have been tampered with, contaminated, or substituted. Secure possession of the samples must be documented from the moment of sample collection (and earlier with regard to reagents, collection bottles and sampling equipment) until results are reported in court. This secure possession must be maintained on a continuous basis as samples are handled by various parties, and is referred to as “chain-of-custody”. Every person who comes into possession of a legal sample should be able to identify the sample and be prepared to testify where he or she received it, when, and from whom. As each person assumes possession of the sample, he or she should mark the date, time, and his or her initials on the sample or to an attached tag. Each person receiving a legal sample should record separately, in a bound notebook kept for this purpose, the sample identification information, date and time of sample receipt, and from whom the sample was received.

Similar information should be recorded in the notebook when possession of the sample is passed to another person. Note that some statutes make provision for taking sufficient quantities of samples so that they may be split between litigants. A number of useful guides have been published as to the special steps and records required for legal samples. Environment Canada, for example, has published useful check list guides towards maintaining chain-of-custody both in the field and during shipping of samples, and also has produced an associated CD-ROM that summarizes the respective roles of samplers, laboratory analysts, legal staff, and expert witnesses. Frank published a very readable summary of the types of records courts expect laboratories to
maintain. Frank also discussed the types of problems that can result when laboratories do not maintain good record-keeping practices. Horwitz (38) noted that assay uncertainty pertains to legal requirements expressed by the terms “preponderance of evidence” and “beyond a reasonable doubt”.

One caution worth noting is that if a record is introduced into evidence, then that record may not be available for other purposes for some years. Also, if a record consists of several pages extracted from a larger record, it might be possible that the other party in court might be entitled to demand the entire document. Therefore, if one is collecting evidence for several different court cases, it is preferable to maintain separate records. Also, extraneous material should be excluded. Finally, it should be kept in mind that the other side will be examining photographic evidence closely for deviations from accepted GSP.

6.2 Certified Reference Materials

CRMs are well characterized materials that have their analyte content guaranteed to be a best estimate by some institution of authority. The certificate accompanying a CRM will describe the purpose of the material, the sample matrix, and the conditions of certification. The certificate may also include other details such as recommended procedures for drying and storage of the CRM. The development and use of CRMs is included in ISO Guides 33 and 35. The development, preparation and utilization of reference materials according to the ISO guidelines is addressed in publications by Mesley et al. (39) and utilization of reference materials according to the in ISO Guides 33 and 35. The development, preparation and utilization of reference materials according to the ISO guidelines is addressed in publications by Mesley et al. (39) and utilization of reference materials according to the ISO Guides 33 and 35. The development, preparation and utilization of reference materials according to the ISO guidelines is addressed in publications by Mesley et al. The development, preparation and utilization of reference materials according to the ISO Guides 33 and 35. The development, preparation and utilization of reference materials according to the ISO Guides 33 and 35. The development, preparation and utilization of reference materials according to the ISO Guides 33 and 35.

A number of publications describe the history, preparation, availability, and appropriate use of CRMs, including papers by Mesley et al. (40) Cantillo and Lauenstein (41) Watters and Koch (42) and Griepink et al. (57)

6.3 Interlaboratory Proficiency Testing

Interlaboratory proficiency testing (also referred to as “round robins” or “collaborative trials”) are collaborative studies where a number of different laboratories (preferably six or more) analyze identical aliquots of one or more stabilized and homogenized large samples. There are two distinctly different types of laboratory proficiency test studies. The first type is intended to determine whether or not a new test method is reliable. These studies usually are of short duration and often are carried out by a small number of participating laboratories, all following identical procedures. The second type of laboratory proficiency evaluation is intended to measure the performance of individual laboratories in comparison with the results of a large number of laboratories. These studies usually consist of a long-term sequence of short-term studies, several per year. Statistics are calculated primarily for each individual study but also for the sequence of studies. Although some interlaboratory studies require all laboratories to follow the same method, usually laboratories are free to use methods of their preference. Laboratory proficiency testing often forms an important part of the laboratory accreditation evaluation. Protocols establishing the minimum requirements for the design, conduct, and interpretation of laboratory proficiency studies have been internationally accepted, based on the recommendations by consensus at the IUPAC Workshop on the Harmonization of Collaborative Analytical Studies held in May 1987 in Geneva, Switzerland.

Four important features of laboratory proficiency studies are currently the subject of debate. First, should the results for individual laboratories be kept confidential by the study organizers? Second, should statistical outliers be removed prior to calculation of method bias and precision? Third, should samples be sent to laboratories on a nonblind basis? Fourth, should laboratories be considered proficient in all methods of determining a particular analyte if they only use their best methods for proficiency evaluations? (To elaborate the last question, if a laboratory has three methods in routine use to analyze some analyte, and one method is substantially
more sensitive and selective than the other two methods, should that laboratory be certified as being proficient in all three methods if only the best procedure was evaluated in a proficiency study? Most laboratory proficiency studies have adopted all four of the aforementioned practices. Horwitz \(^{24,45}\) has reviewed the data from a number of laboratory proficiency testing studies and for a variety of sample matrices and analytical techniques. He discovered that the interlaboratory (i.e. among-laboratory) precision expressed as CV (i.e. relative standard deviation in %) is generally less than twice the values predicted by Equation (5):

\[
CV = 2^{(1-0.5 \log C)} \approx 2C^{-0.1505} \tag{5}
\]

where \(C\) is the analyte concentration expressed as a mass/mass decimal fraction. Horwitz \(^{24}\) reported that this equation (presented in Figure 7) is sufficiently robust for use in checking that interlaboratory studies are themselves in control.

### 6.4 Quality Assurance Concerns for Field Measurements

Field measurements include both measurements made in situ and also measurements or analyses made of collected discrete samples, provided that those measurements are made in the close vicinity to a sample-collection site and soon after sample collection. There are two general categories of field measurements, namely approximate measurements and precise measurements. Approximate measurements are not quantitative and require less operator training and less QC effort. Although approximate measurements are not reliable, they do offer an inexpensive means of ascertaining major characteristics at a site. Approximate measurements are particularly useful in targeting the collection of representative samples in polluted or high-gradient environments. The major flaw to approximate measurements is that they are not reliable and can cause confusion if intermixed with reliable measurements. Therefore, an important aspect of field measurement QA is to ensure that reliable and nonreliable data are unambiguously identified and segregated.

Reliable field measurements require the same detailed QA verification that is required for laboratory measurements. All field instruments should be calibrated under laboratory conditions on a regular basis, and many also require in-field calibration. (It should be emphasized that thermometers and barometers do require calibration.) Even greater effort is required to maintain field instruments in calibration than for laboratory instruments, because of the much greater stress (e.g. vibrations, temperature extremes) encountered by field instruments during transportation and use. Therefore, intensive calibration and calibration reverification are mandatory. Ample time must be given for instruments to warm up prior to calibration and instruments must be protected from temperature extremes, particularly where electronics might be influenced by temperature. Also, many sensors need to reach steady-state conditions with the environment prior to calibration and measurement. The key elements to QA for field measurement include thorough operator training, detailed method manuals, regular laboratory-based calibration and maintenance, intensive on-site calibration checks, audit checks against second instruments and against the results of discrete samples, regular on-site QA audits by a QA Officer or independent party, and detailed records of maintenance, calibration, and use. There are numerous publications regarding SOPs for field measurements. For example, Environment Canada \(^{52}\) has published SOPs that apply across Canada with regard to field inspection of fresh waters. Similarly, Wells et al. \(^{519}\) have published the SOPs followed by the US Geological Survey for field measurements for streams in Texas.

Field measurements must follow the same rigid QA protocols as laboratory analyses, including data management and documentation. QC will depend heavily upon blanks, replicates and reference standards. It must be emphasized that field protocols, SOPs, and associated records must be maintained in weather-tolerant binders, and must be readily accessible in case of accidents or emergencies.

### 6.5 Quality Assurance for Automated Continuous Monitoring

Measurements which are automated, continuous, and in situ have many advantages over the more traditional collection of grab samples. Most importantly, continuous monitoring offers real-time analysis of analytes. This permits transient events to be examined in detail. In addition, continuous monitoring curtails difficulties associated with collecting representative discrete samples and also with sample preservation during transport and storage. This is particularly important with regard to substances that are not readily stabilized. The primary elements of continuous monitors are sensors, controllers, and data loggers. Sensors are devices which produce signals continuously in response either to physical parameters or to concentrations of chemical analytes. Controllers accept the sensor signals, perform various signal conversion and instrument control functions, and pass signal data to the data logger for temporary storage until the information is passed to a central database via a data verification and sometimes a data reduction process. A great advantage of continuous monitors is the large amount of information produced, which is extremely valuable for QA purposes. There is a huge literature
regarding the development of numerous types of sensors, both electronic and fiber-optic based. However, many potential sensors have problems of inadequate sensitivity, inadequate stability, inadequate sensor response time, or inadequate lifetime. Because of these problems, at present only a limited number of sensor types are routinely utilized for long-term continuous unattended monitoring. Camara et al.\textsuperscript{60} have published a detailed summary of this topic, with primary focus upon fiber-optical sensors.

The key elements for continuous monitoring QA generally are identical with those for other field measurements: thorough operator training, detailed method manuals, regular laboratory-based calibration and maintenance, on-site calibration checks, regular on-site QA audits, audit checks against second instruments and against the results of discrete samples, and detailed maintenance, calibration, and measurement records. Whitfield and Wade\textsuperscript{61} have reported from their experiences with automated monitoring in surface waters that standard QA protocols established for sampling and analysis of discrete samples are not adequate for continuous monitors. They suggest that three areas where standard protocols need to be established specifically for continuous monitoring are the problem of field verification, the matter of time controls, and the relationship between sensor accuracy (bias) and precision to frequency of instrument servicing.

6.6 Performance-based Methods

A number of jurisdictions, particularly in the USA and Canada, are adopting “performance-based methods” (PBMs), particularly with regard to sampling and analytical methodologies. For PBMs, a regulatory agency publishes generic methods, with certain key steps specified as mandatory. (For simple target compounds having readily available reference materials, there usually are many mandatory steps. However, for aggregate substances such as petroleum hydrocarbon mixtures, and for substances lacking reference materials, there usually are relatively more mandatory steps.) The regulatory agency also publishes DQOs (such as specific data on recovery, reproducibility, calibration validity, and MDLs) which are to be achieved. The focus of a PBM is on the method per se, and more upon the DQOs associated with the method. Other than the mandatory steps, samplers and analysts are free to use equipment and methodologies of their choice provided that the specified performance criteria are unambiguously proven to have been achieved. The advantage claimed for regulatory agencies is that fewer method SOPs require vetting, that published method manuals do not need to be revised as frequently, and that much of the responsibility and costs of verifying methods is moved from the regulatory agencies to the sampling agencies and analytical laboratories. The advantage claimed for samplers and analysts is that they can readily change methods and equipment in accord with changes in circumstances and advances in technology. The major drawback to PBMs is the substantial initial or front-end transition cost.

Implementation of PBMs in the USA was summarized by Stevenson\textsuperscript{62}. Stevenson noted that “The PBM paradigm is that each member of the characterization and remediation team is responsible for his or her [own] work. . . . It is the job of those involved in the planning, logistics, and storage to have data that demonstrates the entire process complies with the DQO”. The overall PBM process is described by the flow-chart in Figure 8, as it is being implemented in Canada.

6.7 Calculation of Confidence Intervals

If the population distribution for a series of measurements is normal and without nonrandom error, then the probability that the population mean will fall within an interval extending either side of the sample mean can be related to the area under the Gaussian curve within that interval. If one has a sample mean and one knows the population standard deviation, \( \sigma \), then the CI would be given by Equation (6):

\[
CI = \text{mean} \pm \frac{Z\sigma}{\sqrt{n}} \tag{6}
\]

where \( Z \) = probability factor which depends on the level of confidence desired, \( \sigma \) = population standard deviation, \( n \) = number of measurements used to calculate the mean, and mean = sample mean. Usually one does not know \( \sigma \) but must estimate the sample standard deviation, \( s \), from a set of measurements. There are two situations: either \( s \) is determined from the same set of measurements as the sample mean, or \( s \) is determined from another set measurements. For both situations the CI is calculated from Equation (7):

\[
CI = \text{mean} \pm \frac{ts}{\sqrt{n}} \tag{7}
\]

The \( t \) value (sometimes called Student’s \( t \)) is always larger than \( Z \), and corrects for the fact that the standard deviation is not known with confidence for small data sets. The value of \( t \) depends both upon the level of confidence desired and upon the degrees of freedom of the data set used to estimate the standard deviation. The mean must always be calculated from actual measurements, but the population standard deviation may be estimated either from the actual measurements or from measurements of another set from the same population. For environmental studies the mean is often
estimated from only a few measurements, sometimes even from a single measurement. CIs based on a small number of measurements would be fairly wide, and infinitely wide for a single measurement. However, Taylor\(^3\) suggested that for analytical systems proven by control charts to be in statistical control, the values for \(s\) and for \(n\) may be determined from the appropriate long-term QC results. The advantage of employing the long-term QC results to estimate the standard deviation is that often very large numbers of such data are available from the laboratory QC program, thus yielding small \(s\) and large \(n\), and hence narrow CIs. (It is important to note that both \(Z\) and \(t\) are two-tailed for CI calculations but are single-tailed for LOD calculations.)

### 6.8 Control Charts

Control charts provide an understandable means to demonstrate that laboratory analyses are under statistical control, or conversely to diagnose analytical problems for systems which are not in control. Taylor\(^3\) has written an excellent chapter on this topic. Of the several different types of control charts employed by laboratories, the most frequently employed is the Shewhart chart. For these charts, aliquots of some reference material are repeatedly analyzed over time, and the chronological sequence of results are plotted. An example plot is shown in Figure 9.

The central line on the chart corresponds either to the experimentally determined mean for the reference material, or to the certified “true” amount for a CRM. There are several variations to the Shewhart chart. The most common variation has both control and warning limits established on either side of the center line, these limits established according to Equations (8) and (9) or Equations (10) and (11). One or more measurements beyond...
the control limits signals out-of-control conditions and indicates that the analytical method requires remedial attention. Values beyond the warning limit do not require remedial attention unless there is a string of two or more such values adjacent in sequence. There are additional rules to indicate out-of-control conditions, as summarized by Taylor.\(^5\)

Some laboratories choose to plot individual determinations upon their control charts, and other laboratories prefer to plot the mean of several determinations. It is important to distinguish between these two types of Shewhart charts since they employ different algorithms for the control and warning limits, as noted below:

(a) Plots of individual determinations:

\[
\text{control limits} = \pm 3s \\
\text{warning limits} = \pm 2s
\]

(b) Plots of means of \(n\)-multiple determinations:

\[
\text{control limits} = \pm 3s/\sqrt{n} \\
\text{warning limits} = \pm 2s/\sqrt{n}
\]

Another style of control chart is the Cusum chart. For repeated analyses of a reference material, the cumulative sum (hence the name Cusum) of the deviation for each determination from the target mean plus deviations for previous determinations is calculated and plotted sequentially. Each point \(X_n\) on the chart is determined according to Equation (12):

\[
\text{Cusum}(X_n) = \sum_{i=1}^{n} (X_i - \text{mean}_{\text{target}})
\]

These points are plotted either chronologically or in sequence of analysis. Cusum charts tend to be more sensitive than Shewhart charts to some types of problems. However, they are more difficult to comprehend and to program, since the action limits both are not parallel to the axes and also change with addition of each new data point. For this reason the Shewhart charts are more popular. (The author prefers to employ Shewhart and Cusum charts in tandem, but this is an unusual approach.) Garland et al.\(^6\) compared Shewhart, Cusum and other approaches with regard to predictive power of analytical fault detection. They found the Cusum technique to be the most effective. Garfield\(^18\) similarly reports Cusum charts to provide a faster warning of process deviation from control.

A third style of control chart is the range control chart. The distinctive feature of these charts is that they utilize results from actual test samples, whereas Shewhart and Cusum charts utilize results from analysis of reference materials. Range control charts are particularly useful in circumstances where reference materials can be challenged as inappropriate. These charts are employed to monitor measurement precision. However, the deficiency to range control charts is that they do not respond to systematic shifts in measurement response. Range control charts require that a constant number of replicate analyses (usually duplicate analyses) be performed on a routine selection of test samples. The average values for the range, the warning limits, and the control limits are established from statistical analysis of the initial eight or more [Taylor\(^3\) prefers 15 or more] replicate sets. Taylor\(^3\) has summarized this method in some detail, and also has summarized several additional types of control charts not included in this article.

### 6.9 Laboratory Automation

Most laboratories now employ “laboratory information management systems” (LIMS) to automate data management. Jobs performed by LIMS include the preparation of work lists, sample tracking, instrument calibration, verification of QC samples, and delivery of results and invoices to clients. Increasingly sophisticated statistical techniques and graphic presentations are becoming available to both bench analysts and to laboratory QA Officers. Much of the literature regarding LIMS, e.g. Peak et al.,\(^64\) focuses upon their successful employment to review QC results. This past decade has seen considerable improvements in both computer hardware and software utilized for LIMS, and an increasingly larger proportion of routine analysis is being automated. Reports supplied to clients can now include QA verification information and custom formats as specified by the clients. Additional benefits of laboratory automation include reduction in transcription errors, automatic verification against site-specific historical results, production of archive information, and more efficient billing. Benefits to clients include on-line access to preliminary results and tracking of cost estimates for work in progress. Benefits to laboratories include facilitation of audit trails, facilitation of system validation, timely access to original test results and to associated QA/QC data, plus convenient access to methodology information.

Drawbacks to laboratory automation include difficulties in intermarrying hardware and software from different vendors and of different vintage. This is a continuing problem because of the present rapid pace of technological change with regard to computers, instrumentation, and associated software. A second drawback is the increasing workload for computer experts to keep these systems operational as they become increasingly more sophisticated. The following factors are important considerations when establishing a new LIMS system:

- convenient installation and set-up
- convenient upgrade and expansion
• flexible configuration
• documentation complete and regularly updated
• long-term commitment by computer, instrument and software vendors
• timely support by vendor technical staff
• system easy to learn and use
• system security
• flexible retrievals to reflect specific requirements by different clients
• internet and intranet access.

QA for LIMS includes comprehensive records as to hardware and software, timely identification and resolution of problems, routine challenge of LIMS elements, and independent audits by external LIMS experts. A laboratory’s QA manual should include well documented policies and procedures regarding data management via LIMS: data records to be maintained, handling of absent and nonconforming results (including client notification), data reporting formats, special rules for low-level results and for calculated results, data validation, test report content, procedures test report revision, test report authorization, transmission of results to clients, transmission of revisions to clients, access to records, confidentiality of records, and disposal of records. The main focus of QA with regard to LIMS must always be protection of the results. Is there mandatory tracking of all revisions to results? Is there adequate protection against power failure and against introduction of computer viruses? Is there off-site backup in case of fire or earthquake?

ACKNOWLEDGMENTS

DISCLAIMER

The opinions expressed in this article are those of the author and are not the policy of the author’s employer, the BC Ministry of Environment, Lands and Parks.

LIST OF SYMBOLS

\[ \sigma \] Population standard deviation
\[ \alpha \] Probability of type I error, the rejection of a true null hypothesis (e.g. concluding an analyte is present when in fact it is absent)
\[ \beta \] Probability of type II error, the failing to reject a false null hypothesis (e.g. concluding an analyte is absent when it is in fact present)
\[ C \] Analyte concentration expressed as a mass/mass decimal fraction
\[ n \] Number of measurements used to calculate the mean
\[ s \] Sample standard deviation
\[ t \] Student’s \( t \), the value of which is determined by both the level of confidence specified and the degrees of freedom upon which the standard deviation is based
\[ Z \] Probability factor, the value of which depends on the level of confidence specified

5 Inductively Coupled Plasma Mass Spectrometry
6 Anodic Stripping Voltammetry
7 X-ray Spectrometry
8 Neutron Activation Analysis

This article focuses on biological sample preparation methods which are unique to each of the commonly used instrumental techniques used in trace element analysis. The biological samples covered are mainly of human and animal origin. The preparation methods considered span the entire gamut and include direct solid or liquid sample introduction involving dilution or matrix modification; dry ashing; wet oxidation including microwave digestion and high-pressure ashing; deproteinization; and tissue solubilization. The instrumental techniques covered are flame atomic absorption spectrometry (FAAS), graphite furnace atomic absorption spectrometry (GFAAS), inductively coupled plasma atomic emission spectrometry (ICP-AES), inductively coupled plasma mass spectrometry (ICP-MS), X-ray fluorescence (XRF) spectrometry, neutron activation analysis (NAA) and anodic stripping voltammetry (ASV). The choice of a given sample preparation method would be governed in general by the type of biological matrix, sample size and the type of instrumental technique used. The advantages and disadvantages of the various sample preparation methods have been emphasized for each of the instrumental techniques. Also, an attempt has been made to point out the optimum sample preparation method(s) suitable for the particular biological matrix and instrumental technique.

1 INTRODUCTION

The sample preparation method to be used for a given analysis will be governed by the nature and concentration of the analyte, the nature (solid or liquid) and type of biological matrix, the sample size (amount or volume available) and the type of instrumental technique.
used. Generally, solids will require some form of digestion/dissolution, although direct analysis may be feasible with many of the spectroscopic techniques. Liquids may be amenable to direct analysis, but matrix interferences in many cases may necessitate some form of sample pretreatment. This article will focus on sample preparation methods which are unique to each instrumental technique. The instrumental techniques covered are FAAS, GFAAS, ICPAES, ICPMS, XRF spectrometry, NAA and ASV, since they are most commonly used in biological trace element analysis. These preparation methods, which are strictly confined to samples of human and animal origin, have been discussed in detail elsewhere recently with literature citations covering the period to 1993. Therefore, the present treatment will be brief, and literature citations will be primarily restricted to the period since 1993. For sample preparation methods dealing with botanicals and botanically derived products, the reader may refer to the book by Rossbach et al.

2 FLAME ATOMIC ABSORPTION SPECTROMETRY

2.1 Introduction

The sample preparation step is a major concern in atomic absorption spectrometry (AAS) as it basically governs the analytical performance characteristics, namely detection limit, accuracy, precision, speed, throughput and cost. Because of the selective nature of AAS, classical preparatory work, i.e. complete decomposition of organic matter followed by separation and preconcentration of the analyte(s) from the matrix and other concomitants, is not mandatory.

The choice of FAAS or GFAAS depends on the concentration of the element sought and the analytical sensitivity. Table 1 presents a guide to the relative sensitivities of these two techniques. Generally, elements coded A can be measured using FAAS with relative ease, those coded B and C are progressively more difficult and those coded D are impossible with FAAS. The relative lack of sensitivity of FAAS restricts its use to those coded A, namely Na, K, Ca, Mg, Li, Au, Cu and Zn. However, the practical advantages of FAAS such as speed, simplicity, precision, cost and ease of operation are ideal and necessary for the many situations where large throughput is required for the diagnosis and management of a patient’s clinical condition. Thus, many practical measurements in clinical laboratories, hospitals, occupational health, toxicology and nutrition involve FAAS.

For details on FAAS sample preparation methods, the reader may consult a recent book, Atomic Spectroscopy (a Perkin-Elmer publication), which publishes twice yearly a bibliography with the papers being listed in alphabetical order of authors, and the Journal of Analytical Atomic Spectrometry, which publishes AAS updates.

The major FAAS sample preparation methods are dilution, deproteinization, acid extraction, chelation/solvent

Table 1 A guide to the choice of FAAS and GFAAS for the determination of elements in biological materials, especially blood and serum.

a Adapted from Iyengar et al.
b A, easily determinable by both FAAS and GFAAS (requires <1 mL of sample by FAAS and <10 µL by GFAAS); B and C, progressively more difficult (B requires 1–10 mL by FAAS and 10–50 µL by GFAAS while C requires 10–100 mL by FAAS and 50–1000 µL by GFAAS); D, extremely difficult by FAAS and difficult by GFAAS (>100 mL by FAAS and > 1000 µL by GFAAS). The volumes required are for the generation of a signal of 0.05 absorbance unit from either a dilution/concentration to 1 mL for FAAS or a direct injection with a practical upper limit of 50 µL for GFAAS. The volumes are based on the mid-range of reference levels for the essential, the lower end of the target range for the therapeutic and the upper limit of acceptable levels (in the case of ‘nonexposed’ individuals) for the nonessential elements.
2.2 Dilution

Dilution methods are mainly used for biological fluids, especially serum and urine. The main function of diluents is to overcome the viscosity effect of the matrix (e.g. protein content of blood) on the sample uptake rate. Simple aqueous or acidic (0.1 M HCl) dilutions that can be used to overcome this effect are 50-, 12- and 5-fold for whole blood, serum and urine, respectively. The acid concentration used in dilutions should be as low as possible. Solutions with acid concentrations ≥5% should be nebulized using a nebulizer with a Pt-Ir capillary. With relatively low temperature flames, the addition of La(III), Sr(II) or ethylenediaminetetraacetic acid (EDTA) is necessary to overcome the suppressive effect of phosphate on Ca absorption and the influence of ionization on Na and K. For example, Ca, Mg, Na and K can be determined by a 50-fold dilution of serum with 0.25% SrCl₂.

In direct and dilution procedures, the viscosity and solids content of biological fluids must be such as to permit nebulization without giving rise to problems associated with variation in aspiration rate, burner blockage or nebulizer ‘salting-out’. The long-path air-acetylene burner head will accommodate 2–3% solids at 40 psi oxidant pressure, and up to 10% solids by progressively reducing the oxidant pressure. In many cases, however, the design of the nebulizer, premix chamber and burner may not permit complete removal of the matrix effect caused by the protein in serum, especially at dilution factors <10, and compensating factors may have to be introduced. These include the addition of butanol, acetone or Triton X-100 to the diluent, deproteinization and comparison with aqueous standards, positive pressure sampling and matching the viscosity of standards to that of the plasma by the addition of glycerol.

Considerable variation in the protein content of plasma occurs among normal subjects and very wide differences occur between normal and pathological specimens. In most chronic diseases, the albumin content falls substantially, and to obtain accurate results, separate standards of appropriate concentrations have to be prepared. Hence the technique of loading standards with a protein-like material to match the sample viscosity cannot be considered suitable for clinical work, and simple dilution of the sample is recommended. Since significant alterations in aspiration rate can occur even when plasma is diluted 10-fold, a minimum dilution of 12-fold is recommended. Reduced signal strength may require scale expansion leading to an unstable baseline, but this problem can be overcome by employing a strictly timed sequence of measurements. Matrix effects may be pronounced, requiring matrix-matched calibration. Fortunately, the matrix properties of blood and serum are constant, and calibration solutions can be prepared in pooled spiked blood or a few previously analyzed specimens can be used as standards. Flow injection analysis (FIA) in conjunction with FAAS can used to facilitate automatic sample handling such as online dilution and buffer additions, reduction in sample consumption and a minimization of interferences arising from sample viscosity.\(^{(1)}\)

2.3 Protein Precipitation (Deproteinization)

Protein precipitation involves removal of protein from serum and blood by precipitation with a reagent such as trichloroacetic acid (TCA) and FAAS analysis of the supernatant fluid. TCA, employed as a 5–10% solution, is the most popular reagent. Elements determined by this method include Cu, Fe and Zn. However, the TCA precipitation method for Cu and Zn gives higher values than the dilution method owing either to volume exclusion errors or to some nonspecific interferences. There seems little value in using the TCA method in view of the established accuracy of the dilution procedures.

2.4 Acid Extraction

Zinc could be quantitatively extracted from homogenized diet and feces samples with 1 M HCl. This simple yet efficient method can be extended to other metals in diets and feces. Quantitative release of Mn from liver homogenates with 10% Triton X-100 could be obtained heating for 1 h in 2 M HCl at 60°C. Extraction of bovine liver with 1% nitric acid gave quantitative recoveries of Cd, Cu, Mn and Zn.

2.5 Chelation/Solvent Extraction

When the analyte concentration falls below the detection limit or is low enough to make a precise direct determination impossible, preconcentration by solvent extraction is used in conjunction with FAAS to concentrate the analyte (by reducing the solvent/aqueous phase volume ratio) or to remove matrix interferences, or both. Also, organic solvents generally produce an enhanced signal in the flame. The most popular chelating agents are sodium diethyldithiocarbamate (NaDDC) and ammonium pyrrolidinedithiocarbamate (APDC) because they complex with many metals. Also, a concentration factor as high as 100 is possible with APDC, and the analyte can be easily separated from the biological matrix which
may cause difficulties with nebulization and atomization. The most widely used solvent is methyl isobutyl ketone (MIBK) because of its extraction and nebulization efficiencies, combustibility and high enhancement factor. If required, selective extraction can be performed by adjustment of the sample pH and use of more specific chelating agent/solvent systems. In this way, a particular metal which may cause subsequent interference in the flame analysis can be removed or the analyte under consideration can be isolated from the matrix. Delves et al.\(^3\) used this approach to extract sequentially 11 metals from 1 mL of blood.

The solvent extraction approach should be used only when the sensitivity of direct procedures is inadequate, severe matrix effects are to be avoided or certain specific chemical species or binding state of the analyte are being studied. This is because it is tedious and prone to risk of contamination. Nowadays, solvent extraction methods in FAAS methods are used mainly for the concentration of low levels of metals from urine and tissue specimens after destruction of organic matter. Extractions are most efficiently performed on ashed samples in which the analyte is converted into an ionic form, but some elements, such as Cd, Ni, Pb and Tl, have been extracted from blood hemolyzed from Triton X-100 or from the supernatants of TCA-deproteinized blood or serum. Ashing prior to extraction is certainly required for As, Au, Hg and Se since they are strongly bound to the organic matrix.

Recent preconcentration studies using FIA for on-line solid sorbent extraction and subsequent FAAS detection seem very promising.\(^4\) The combined advantages of automation, speed, microsample requirement, preconcentration, separation of analyte from matrix coconminants and sensitivity enhancement by the organic solvents permit several elements to be determined by FAAS which were previously accessible only by GFAAS, and which thus seem to be ideally suited for clinical application. The on-line extraction of Cu and Cd in urine as the diethylthiocarbamate (DDTC) complexes on reversed-phase C\(_{18}\) immobilized on silica gel and elution into the FAAS system using ethanol, the on-line ion-exchange preconcentration of Al in dialysis fluids and the determination of Pb in acid-digested blood and liver samples by on-line coprecipitation with the hexamethylenammonium hexamethylenedithiocarbamate (HMAHMDTC)–Fe(II) complex are typical examples.\(^4\) The coprecipitation procedure has also been used for the determination of Cd, Co and Ni in blood, urine and animal and plant tissues. The procedure is unique in that the precipitate was collected on the walls of a knotted reactor made of 150 cm of Microline tubing of 0.5 mm i.d. The precipitate was dissolved in a stream of MIBK which was fed directly into the flame. The preconcentration factor, signal enhancement factor, coprecipitation time and sampling frequency were 20, 66, 30 s and 90 h\(^{-1}\), respectively. On-line preconcentration has become even more attractive since it could be combined with on-line sample digestion, as has been demonstrated in the case of Bi, Hg, Pb and Sn in urine.\(^4\)

### 2.6 Destruction of Organic Matter

The introduction of tissue specimens into an FAAS system necessitates conversion of organic matter to a relatively simple inorganic form in solution. Wet digestion and dry ashing are the two main techniques employed in tissue destruction. Wet digestion methods include decomposition by acids either alone or in mixtures carried out in open vessels in tubes on a hot-plate or aluminum heating block, and in closed vessels at increased pressure via a bomb or high-pressure asher (HPA) or microwave heating. Microwave digestion is an attractive method, especially for small samples. The simplest dry ashing technique for the preparation of tissue specimens is to ash the sample in a conventional muffle furnace at \(<600^\circ\text{C}\), usually with some type of ashing aid. This approach often leads to contamination and loss of analytes, and thus has tended to fall from favor. Acceleration of the reaction can be accomplished for small samples by heating at \(<150^\circ\text{C}\) in an atmosphere of radio frequency-generated oxygen. This low-temperature ashing (LTA) minimizes the loss of volatile elements.

In general, complete oxidation of organic matter is not necessary (but see below) for FAAS work as long as the analyte is quantitatively brought into an appropriate acidic solution, and the blank level can be reduced. FAAS tolerates any acid up to a concentration of \(<5\%\). The majority of the procedures involve HNO\(_3\), but HCl and HCl + HNO\(_3\) are also effective. Complete digestion is essential for those elements which are most prone to volatile loss, namely As, Ge, Hg, Sb, Se, Sn and Te. In these cases, wet digestion should be performed under carefully controlled conditions. The completeness and speed of these digestion procedures can be enhanced by using pressurized vessels; also, they minimize blanks and loss of volatile elements.

The concentration of many elements (e.g., Co, Cr) in tissue samples is greater than that in body fluids, and it is possible to determine them by FAAS. Many digestion procedures are available, but the HNO\(_3\) + HClO\(_4\) procedure described by Taylor is satisfactory for elements such as Na, K, Ca and Mg.\(^1\) Blanks can be minimized by using small sample sizes, pure reagents and labware materials, thorough cleaning, shorter digestion times, using reflux conditions or closed vessels, low temperature, controlled heating and clean air conditions.
2.7 Hydride-forming Elements
Conventional FAAS offers poor sensitivity and is prone to interferences for the hydride-forming elements such as As, Se and Sb. However, measurements via the hydride-generation reaction circumvent these problems and provide a useful method for the determination of these elements at trace and ultratrace levels.\(^4\) The formation of the hydride requires that the element in the sample should be present in ionic form. Hence the destruction of organic matter to provide a simple inorganic matrix is necessary prior to hydride generation. The majority of published work prefers acid digestion using HNO\(_3\), H\(_2\)SO\(_4\) and HClO\(_4\) to accomplish this. Loss of analyte during digestion is more of a potential problem and recovery studies indicate that it is crucial to ensure that the digestion vessel has a sufficiently long neck (Kjeldahl tube or tall boiling tube) to act as condenser and to prevent excessive heating, or to use a closed pressure digestion vessel. The preparation of specimens for the digestion with H\(_2\)SO\(_4\) by controlled reduction. As and Sb must be reduced to As, Sb, Se and Te, the oxidative attack must be followed by an alkaline solution of NaBH\(_4\) to prevent the premature loss of mercury during the addition of the reductant. Magos developed a direct method for total Hg and SnCl\(_2\) alone for inorganic Hg in blood, urine, tissues, foodstuffs and feces.\(^4\) Determination of Hg at the lowest level (down to 3 ng L\(^{-1}\)) requires preconcentration and separation. The collection of Hg as an amalgam on a gold or silver gauze adsorber is the most common approach.\(^4\) Collection from large sample volumes and/or over extended periods of time permits high concentration factors. The Hg is released for determination by electrically heating the amalgam at 600°C.

2.9 Tissue Solubilization
Tissue solubilization with tetramethylammonium hydroxide (TMAH) is simple, permits large throughputs, gives a clear, homogeneous solution, offers two- to fourfold improved sensitivity due to the organic solvent effect and avoids hazards intrinsic to certain wet digestion procedures. TMAH is commercially available in aqueous, alcohol, 1-propanol, toluene and other solvents such as Lumatom, Soluene 100 and Soluene 350. Typically, 0.1–1 g of dry sample is solubilized with 1–5 mL of TMAH in 8–48 h at ambient temperature or in 2–8 h at 50–70°C. Occasional agitation is useful. Homogenates are further diluted with water, alcohol, MIBK, etc. as required, just prior to analysis, and then fed directly into the flame for Cd, Cu, Fe, Mn, Pb and Zn determination in liver, brain, placenta, etc.\(^1\) Some workers have found that addition of APDC (25% alcoholic solution of TMAH in 2% APDC) minimizes losses of metals. Standard addition calibration is required. Some of the disadvantages of TMAH solubilization include limited time stability of the homogenates compared with the acid digestates and prolonged digestion times.

2.10 Solid Sampling
Some work exists on the use of solid sampling techniques for the FAAS analysis of tissue samples.\(^1\) Large samples (9 g of liver or beef steak) were processed in a Brinkman Polytron stainless-steel homogenizer to yield low- to submicrometer diameter aqueous homogenate particles (~60% solids). A 500-μL aliquot of the diluted (13% solids) homogenate was injected into a Babington clog-free, high-solids nebulizer. Cu, Mn and Zn were determined by this approach in an air–acetylene flame using the method of standard additions.

2.11 Methods for Various Elements
It is important to emphasize that interferences associated with viscosity in the case of ionizing elements are influenced by nebulizer and burner designs. Not every method listed below will, therefore, transfer directly to all atomic absorption (AA) instruments. Analysts are advised to test for these interferences and ways of removing them. The methods given here refer to specimens and analytes routinely examined. For the not-so-common
preparation methods, and for details on individual elements, the literature should be consulted.\(^{(1,5–7)}\) The element groupings listed below are based on the Delves classification.\(^{(8)}\)

### 2.11.1 Electrolyte Elements Sodium, Potassium, Calcium and Magnesium

Table 2 presents the volumes of blood, serum or urine required for the FAAS determination of the physiological levels of these elements. The relatively high physiological concentrations and the good FAAS sensitivities of Na, K, Ca and Mg allow sufficiently high dilutions of the biofluids to overcome all viscosity and surface tension interferences. Typical serum dilutions are 1 + 249 for K and 1 + 99 for Na with the addition of Li or Cs as ionization suppressant, and 1 + 49 for Ca and Mg with the addition of a releasing agent such as La (usually 0.01 M La in 0.05 M HCl) to eliminate matrix interferences from phosphate. The determination of these metals in urine can be done using even higher aqueous dilutions than those for serum specimens. Note that flame emission is the preferred method for Na and K, although FAAS is equally good. This is mainly because many commercially available flame emission instruments specifically designed for the simultaneous measurement of Na and K are available.

\(^{b}\) S = serum; P = plasma; U = urine.

\(^{c}\) The use of Li as internal standard affords good analytical control.

\(^{d}\) Hemolysis or failure to separate plasma from cells within about 4 h causes release of K from erythrocytes and the results will be erroneously high. Unreliable results can be obtained for K with serum, and plasma is recommended for this determination.

\(^{e}\) Addition of La overcomes phosphate interference. EDTA or Sr(II) may also be used. A dilution factor > 50 may be required for urine from individuals who are hyperexcretors of Ca and Mg.

\(^{f}\) Wilson’s disease patients will have high Cu excretion requiring appropriate dilution of urine.

\(^{g}\) Precipitation solution is composed of 10% TCA, 3% thioglycolic acid and 16.6% HCl. Sample preparation procedure for total iron binding capacity (TIBC) is given in Taylor.\(^{(9)}\)

\(^{h}\) Procedure given is for Fe in urine following chelation therapy.

\(^{i}\) Serum should be used for Li measurement since lithium heparin is a widely used anticoagulant, and plasma may be grossly contaminated with Li.

**Environmental Water and Waste**
of the supernatant with 0.5 mL of acetone to overcome viscosity interference and FAAS analysis. The use of TCA in place of ascorbic acid was not satisfactory because it could not remove the interference from NaCl at the 248.3-nm line. Urine Fe measurement requires solvent extraction and preconcentration. The high background at the 196-nm line and the poor sensitivity preclude the use of conventional FAAS for measuring Se in biological materials. Hydride generation techniques have resulted in sensitive methods.\(^9\)

The determination of Mn in serum, whole blood and urine by FAAS requires considerable improvement in detection limit through preconcentration. Therefore, scrupulous control of contamination would be essential. Delves determined Mn in 2-mL samples of whole blood after \(\text{HNO}_3 - \text{HClO}_4 - \text{H}_2\text{SO}_4\) oxidation and extraction at pH 8.5 with 8-hydroxyquinoline (oxine)–MIBK.\(^8\) A fourfold concentration allowed measurements to be made down to 50 nM. Van Ormer and Purdy analyzed 100-mL volumes of urine after acid digestion and extraction with cupferron at pH 7 with 30 mL of MIBK.\(^\text{1}\) They could detect down to 1.8 nM. Many other chelating–extraction schemes have been employed.\(^8\) Analyses of metals such as Co, Cr, Mo and V require some form of pretreatment to provide absorbance signals of sufficient magnitude to allow precise measurement of reference ranges. Since FAAS analyses of these metals in biofluids require preconcentration from large volumes, alternative techniques such as GFAAS are more appropriate.

Digestion and dissolution, solubilization or acid extraction are the possible approaches for diets, feces and tissues.\(^1\) In the case of electrolyte elements, a simpleashing procedure prior to dilution will suffice. An attractive procedure for the determination of Zn in diets and feces without sample oxidation involves acidification of the samples with 6 mL of 1 M \(\text{HCl}\) for 24 h, extraction of the fatty components with chloroform and centrifugation of the solution after the addition of methanol to reduce surface tension. Tissues such as liver and kidney which are rich in elements such as Cu, Zn, Fe and Mn are also amenable to FAAS analyses.

### 2.11.3 Therapeutic Elements Gold and Lithium

The FAAS of Au in the serum of arthritic patients receiving chrysotherapy can be carried out easily by a 1 + 2 aqueous dilution because of the high concentrations encountered. However, solvent extraction methods are advisable owing to matrix interference problems.\(^1\) Li can be determined by a 25-fold aqueous dilution of serum because of its high therapeutic range (0.8–1.5 mM). No matrix problems are encountered at this dilution.

### 2.11.4 Nonessential Elements Lead, Cadmium, Nickel, Arsenic and Mercury

The poor sensitivity of FAAS for Pb precludes its direct determination in blood. FAAS method requires preconcentration, usually by solvent extraction.\(^1\) Lead may be released from blood proteins by TCA precipitation, haemolysis with Triton X-100 or complete acid digestion prior to extraction. Acid digestion as pretreatment for solvent extraction with APDC/MIBK has been used for the FAAS analysis of Pb in tissues, diets and feces. In the case of urine, Pb may be directly extracted at pH 2.8 using APDC/MIBK. The large volumes (5 mL) of blood required for these solvent extraction/FAAS methods will be unacceptable for pediatric work. Pediatric samples may be analyzed by discrete sampling FAAS using the Delves cup method. The procedure involves oxidation of 6 µL of blood with 20 µL of 20% \(\text{H}_2\text{O}_2\) in a nickel cup prior to insertion into an air–acetylene flame. The method could also be used to measure Pb in lung, liver and kidney samples.\(^1\)

The direct determination of Cd in blood and urine is not possible because of the poor FAAS sensitivity. The APDC/MIBK extraction method has been used for measuring Cd in tissues, diets, feces and urine after acid digestion or after TMAH solubilization. However, unacceptably large volumes of blood (at least 10 mL) would be required to measure the very low concentration of Cd (<0.2 \(\mu\)g L\(^{-1}\)) observed in unexposed humans. Discrete sampling FAAS with the Delves cup method may be used to measure Cd in 15 µL of blood down to 0.3 \(\mu\)g L\(^{-1}\). Solvent extraction and preconcentration are necessary to measure the low levels of Ni found in body fluids and tissues. Sunderman et al. have determined Ni by APDC/MIBK extraction of acid digested serum, urine and tissues.\(^1\)

### 2.12 Methods for Urine, Hair, Nail, Feces, Milk, Tooth and Bone

The above discussion mainly dealt with blood components and soft tissues. Given below are sample preparation methods applicable to some of the other matrices.

A urine sample should be vigorously shaken before aliquoting since some elements, such as As, Hg and Pb, tend to adsorb on container walls or coprecipitate with the particulate matter (Cd, Cr, Cu, Hg, Ni, Pb) settled on storage. The urine matrix is so variable that it can give rise to serious and unpredictable matrix effects. Therefore, few elements can be determined by direct FAAS involving only dilution. Also, untreated or inadequately treated urine tends to create foaming problems. Release of the analyte from its chemical bond with the urine matrix or destruction of the organic matter can be attained by complete ashing or by a simple minor
pretreatment of urine with \( \text{HNO}_3 \), TCA or \( \text{H}_2\text{O}_2 \). The latter approach is recommended for its speed, simplicity and lower blank; it is often practised prior to extraction and other preconcentration steps, and in direct assays by hydride generation or cold vapor AAS. Wet digestion and dry ashing methods can also be used.\(^{(1)}\)

One of the preparatory steps in hair analysis is washing.\(^{(1)}\) Ideally, any reliable washing procedure should remove exogenous dirt, adherent air particulates, dead skin and adsorbed vapor (e.g. Hg) without significantly leaching the endogenously incorporated trace elements. A number of washing solutions have been applied, such as water, dilute acid (1\% HCl or HNO\(_3\)), dilute EDTA, detergent solutions, organic solvents, and also different washing conditions, such as soaking, stirring, ultrasonification and heating of wash solution to 100°C. Mild washing with water or detergent solutions closely resembles the usual in situ washing of hair, but has resulted in the partial leaching of elements from hair (e.g. Cu, Fe, Rb, Zn, Ca, Cl, Na, K, Mg). Organic solvents effectively remove grease and fat with little extraction of the trace elements. Ether, acetone and ethanol are most often used, but have been criticized as unnatural and ineffective. Strong washing solutions such as EDTA and acids are not recommended as they extract both the trace elements and inorganic matrix components of hair. Even aqueous solutions of detergents with \( \text{pH} < 6-7 \) have been found to leach trace elements. For the sake of standardization, many analysts follow the International Atomic Energy Agency (IAEA)-recommended procedure of washing, which consists of five successive washes, namely acetone–water–water–water–acetone, each for 10 min in 25 mL of solvent.\(^{(1)}\) However, this has also been criticized. In summary, there is no consensus on the washing procedure for hair. The main difficulty arises in cases of major exogenous contamination, especially with the determination of ubiquitous elements such as Al, Cr, Fe, Mn, Ni, Pb, Si and V.

Homogeneous pools of hair can be prepared by cutting hair into 2–3-mm pieces or by grinding at liquid nitrogen temperature.\(^{(10)}\) Hair can be brought into solution by acid treatment or TMAH solubilization. Generally, 10–50 mg of the sample are digested with \(<1 \text{ mL of HNO}_3 \) in small test-tubes which can be screw-capped or pressurized. The resulting HNO\(_3\) digests are diluted and injected directly into the flame for determination of metals such as Cu, Fe and Zn. In the case of volatile elements such as As, Se and Hg, complete digestion may be required; this can be accomplished using HNO\(_3\)–H\(_2\)O\(_2\) or HNO\(_3\)–HClO\(_4\) prior to hydride generation or cold vapor AAS. In the case of TMAH solubilization, usually 50-mg specimens are incubated at 50°C with 0.1 mL of water and 1 mL of base (Soluene, Lumatom, etc.) for 3–24 h, and the contents are subsequently diluted with alcohol or toluene.

Dry ashing of hair at 450°C, followed by dissolution of the ash in HNO\(_3\), is also practised in the determination of non-volatile elements in larger samples. Nail specimens are, in general, found to be more severely contaminated with metals than hair, and hence require more thorough cleaning. The surface layer is scraped off using a quartz or titanium knife, a platinum-coated razor blade or Teflon\(^{\circledR}\)-coated forceps. This is followed by cleaning in an aqueous nonionic detergent or an organic solvent, or both. Application of heating or ultrasonic during washing is also practised. Nail specimens are easily digested with HNO\(_3\), HNO\(_3\)–HClO\(_4\) or HNO\(_3\)–H\(_2\)SO\(_4\). For most nonvolatile elements except noble metals, TMAH solubilization is also useful. Complete digestion will be required for volatile elements.

In the case of feces analysis,\(^{(1)}\) thorough homogenization is required because of the highly variable composition. Feces can be homogenized by adding an equal amount of water followed by shaking for a few hours. Alternately, homogenization can be effected by the brittle fracture technique, which involves grinding or shattering at liquid nitrogen temperature. Smaller samples can be ground after lyophilization. The homogenates should be stored deep-frozen or lyophilized or refrigerated if analysis is to be deferred. Feces are a difficult matrix because of their high content of organic matter, especially fat, and the inorganic salts, especially those of Na, K, Ca and Mg. In order to destroy the fat content completely, digestion with a mixture containing HClO\(_4\) or H\(_2\)O\(_2\) is desirable. Typically, 1–2 g of feces is digested with 10–15 mL of HNO\(_3\) with controlled heating followed by oxidation with HClO\(_4\) or H\(_2\)O\(_2\). Several other wet ashing procedures have been described by Tsalev.\(^{(1)}\) Acid-extraction procedures involving incomplete digestion of organic matter have also been described. Dry ashing of feces at 450°C has been applied, but insoluble residues of oxides, phosphates and silicates tend to persist, giving rise to problems during FAAS analysis. Also, volatile elements such as As, Cd, Cu, Hg, Pb, Se and Zn are not quantitatively recovered.

In general, milk\(^{(1)}\) is a difficult matrix owing to its high and variable fat content (approximately 4% maximum) and inorganic salt content, especially of Ca, K and P. Fat is not completely decomposed by most conventional wet digestion procedures. Hence pressurized decomposition in polytetrafluoroethylene (PTFE)-lined bombs with HNO\(_3\) or HNO\(_3\) + V\(_2\)O\(_5\) is advisable. Combustion in oxygen is an effective technique for volatile elements such as As, Hg, Sb, Se, Sn and Te. Other approaches include dilution of the sample with an aqueous detergent such as 0.1% Meritens (nonyl phenyl polyglycol ether), 0.1% saponin or 0.05% Triton X-100 for Cu, Fe and Zn, protein precipitation with TCA acid for Cu, Fe and Zn and acid extraction with 1–2 M HCl for Mn and Pb or H\(_2\)SO\(_4\).
for Cd, Cu and Fe.\(^\text{(1)}\) Dry ashing at 450–500 °C is often practised owing to its simplicity, thorough fat oxidation and applicability to many elements. Depending on the individual element to be quantitated, the ash may require further treatment with acids. Tsalev\(^\text{(11)}\) has detailed the procedures available for the various individual elements. Preconcentration and separation from the matrix are often required for Cd and Pb, and especially for Ag, Bi, Co, Sn and V.

In the case of teeth,\(^\text{(1)}\) the sample is scraped from adherent soft tissue and tartar using polyethylene (PE) or PTFE instruments, then washed in high-purity water with a stiff plastic brush and finally rinsed with high-purity water. In determining elements such as Cd and Pb, the quantitative separation of dentine and enamel is essential since these elements are higher in dentine by one to two orders of magnitude. One of the most popular techniques for the separation of enamel and dentine involves powdering the tooth by crushing and grinding, mixing the powder with a heavy fluid such as bromoform, ultrasonification and then centrifugation. Another density separation may be required to remove the carious tissue. Pressurized digestion with HNO\(_3\) in PTFE-lined bombs is the most popular digestion method for dissolving small specimens of tooth enamel. Whole tooth and bone, which contain more organic matter and fat, are digested with combinations of acids: HNO\(_3\) + HClO\(_4\), HNO\(_3\) + HCl + H\(_2\)O\(_2\), etc. Rapid microwave digestion of teeth with a mixture of HNO\(_3\) + HClO\(_4\) + H\(_2\)SO\(_4\) has also been described. Only Fe, Sr and Zn, and perhaps Mn and Pb, can be determined directly in the bone/tooth digests by FAAS. Because of matrix effects in these direct techniques, matrix-matched calibration should be used. Determination of Cd, Cu and Pb is best effected by chelation–extraction of the digested bone or tooth. Coprecipitation methods have also been described for Ba and Sr.\(^\text{(11)}\)

3.2 Direct Methods

Direct methods seem ideal for laboratories engaged in the routine analysis of a large number of samples because they are simple and rapid, involve little sample pretreatment, reduce the risks of contamination and do not require considerable operator skill. Earlier publications advocated direct injection of microliter volumes of biological fluids such as blood or serum into the furnace. However, the results obtained were not accurate because of excessive background absorption, carbonaceous residue buildup within the graphite tube and frothing, foaming and splattering of the samples during the drying stage. Hence some form of sample pretreatment was required to obtain reproducible and reliable results.

3.3 Dilution

Biological fluids have been diluted with water, Triton X-100, acids (especially nitric acid) or ammonia. However, aqueous dilution of whole blood is often associated with time-dependent interferences. A precipitate of red cell membrane appears within 1–2 min and reaches a maximum within 15 min. This is of particular importance when large numbers of samples may be prepared hours in advance of the analysis. Dilution of serum, plasma or urine seldom presents serious problems. Dilution factors as high as 50 or 100 can be used for metals such as Cu, Fe and Zn because of their high levels in serum and excellent GFAAS sensitivity. At such high dilutions, matrix effects are insignificant and these three elements can be easily determined in serum with a 50-fold dilution with water. Oxidizing acids such as HNO\(_3\) or HClO\(_4\) at the 1–10% level have been used as diluents for biological fluids to help reduce molecular absorption interferences and as reagents to modify the effect of the matrix upon analyte sensitivity. However, dilution of blood samples with these acids is generally unsuccessful because the protein/red cell precipitation results in a turbid mixture which is more difficult to pipet than the original solution. An often overlooked reagent is dilute ammonia solution. A 1 + 19 dilution of whole blood, using 1% (v/v) ammonia solution, provides complete cell lysis within minutes of mixing, and the diluted samples are stable for up to 48 h when stored at 4 °C.
Triton X-100, a nonionic surfactant, has found widespread use as a diluent because it causes cell lysis, provides a clear homogeneous solution from whole blood, minimizes frothing of whole blood, reduces the sample/graphite interfacial tension and improves the contact between sample and furnace walls. However, this reagent can diffuse into the graphite, leading to variable rates of atomization. The use of a pyrolytically coated graphite tube in conjunction with a L’vov platform can reduce but not eliminate this problem. The concentration of Triton X-100 used has varied from 0.05 to 2%. However, the final concentration injected into the atomizer should be preferably less than 0.25% (v/v). Higher levels of Triton X-100 can cause buildup of a carbonaceous crust within the graphite tube and can degrade the furnace performance.

3.4 Deproteinization

Treatment of diluted whole blood with 3–5% nitric acid leads to complete deproteinization and quantitative release of metals. Centrifugation of the deproteinized samples yields clear supernatant fractions that contain the metals, and which can be easily dispensed into the atomizer using autosamplers. The method is simple, rapid and contamination-free since all operations can be done in the same sampling tube. Other deproteinizing agents used include TCA and HClO₄ (10% final concentration) in acetone. The use of HClO₄ in acetone is potentially hazardous and is not recommended.

3.5 Matrix (Chemical) Modification

A few simple chemical reagents added directly to biological fluids or to tissue digests can minimize matrix effects upon analyte sensitivity either by modifying the volatility of the analyte or of the matrix. The modifier generally allows the formation of a more thermally stable analyte/modifier compound which allows the matrix to be separated from the analyte and removed from the atom cell prior to atomization. Many reagents have been used as modifiers in biological analysis.\(^1\)

The various ammonium phosphates, either alone or in combination with magnesium nitrate, have been used for the determination of Cd and Pb in whole blood and urine. These permit pyrolysis temperatures of approximately 650 and 950 °C to be used for Cd and Pb, respectively. Other matrix modifiers used include Ag, Cu, Ni, Pt, Pd and V. Since Cu and Ni are often determined in biological materials, their use as matrix modifiers is not advisable because of possible furnace contamination. Welz\(^1\) based on his group’s studies and the studies of Ni et al., advocated the use of Pd(II) either alone or in conjunction with magnesium nitrate as a ‘universal’ modifier applicable to as many elements as possible.

3.6 Dissolution of Tissues

Clear homogeneous solutions were obtained when 100–300-mg samples of brain, liver, muscle and placenta were heated at 60 °C with 1–3 mL of a 25% alcoholic solution of TMAH containing 2% APDC, and the cooled solutions were diluted with toluene. The solutions were analyzed for Cu, Fe, Mn, Pb and Zn. Although 26 different types of tissues have been dissolved using only a 25% alcoholic TMAH solution followed by water dilution, the standard solutions of metals formed precipitates with the basic TMAH in the absence of APDC. Therefore, the use of TMAH in conjunction with APDC is recommended.

3.7 Complete Oxidation of Tissues and Fluids

The procedures mentioned in sections 3.1–3.5 are applicable only to biological fluids, and not to tissues. In the case of tissues, it is necessary to oxidize them completely using either hot mineral acids (wet ashing) or by prolonged heating at elevated temperatures (dry ashing) prior to bringing them into solution suitable for analysis. The book by Tsalev\(^1\) may be consulted for the various combinations of acids used in wet digestion. Particular mention may be made of vapor-phase oxidation and pressure digestion. The sample is placed inside a reaction vessel containing nitric acid and fitted with a reflux condenser. The sample attack, which takes 3–4 h, is from the vapor phase only, ensuring that no acid accumulates in the sample and the contamination is minimized. The digestion of tissues can be accomplished rapidly by heating the tissue samples to 110–170 °C with oxidizing acids in sealed pressure vessels. The process can be made especially faster using microwave heating, which has become very popular in recent years.

Dry ashing of samples in muffle furnaces is rarely used because of potential contamination, analyte loss and possible matrix effects because of the high levels of the dry ashing aids (e.g. magnesium salts) used. LTA using gas mixtures such as ozone or carbon tetrafluoride in oxygen seems very effective for the decomposition of biological tissues and blood, and merits further study.

All the sample preparation methods described above may be used with solvent extraction and other separation techniques to concentrate the analyte and separate it from the matrix.\(^1\) However, the potential for contamination with preconcentration is great with a sensitive technique such as GFAAS. Nevertheless, two preconcentration approaches are worthy of mention. The on-line FIA coprecipitation system mentioned earlier in connection with FAAS has been adapted for the GFAAS determination of Cd and Ni in digested whole blood. The small sample volumes of 0.12–0.15 mL (1.2–1.5 mL of digest) required for the preconcentration make it ideal for sample-limited applications such as pediatric blood
and serum analysis. In the second approach, the gaseous hydrides generated in a continuous or flow injection system are introduced via a quartz capillary into a graphite tube atomizer coated with a palladium–iridium modifier where the hydrides are decomposed and the metalloid atomized. This approach not only gives high sensitivity because of the preconcentration, but also eliminates any kinetic interferences in the generation stage by separating it from the atomization step.

3.8 Solid Sampling

Solid sampling is an attractive approach for the GFAAS analysis of biological tissues, especially hair, nail, bone, teeth, etc. Direct introduction of solid tissues into the graphite furnace has several advantages, including shorter sample preparation time compared with dry ashing or wet digestion, minimal sample contamination, reduced loss, especially of volatile elements, and increased sensitivity. The enhanced sensitivity is particularly useful when only small amounts of sample are available for analysis. Herber has summarized the feasibility of the solid sampling approach for the determination of a number of elements in biological materials. Readers may also consult the proceedings of four European colloquia on solid sampling. Solid sampling has been applied to the determination of Al, As, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, Se and Zn in biological tissues, especially liver and muscle. Soft tissues such as liver, muscle and kidney need only freeze-drying and subsequent milling. Hair may be crushed by adding liquid nitrogen and stirring with a quartz rod. Hard tissues such as bone and teeth can be treated with liquid nitrogen followed by milling or pulverizing. Suitable milling devices can be made from agate, carbide or titanium. Calibration may be performed against natural or synthetic solid standards, against standard addition or against aqueous standards. Herber has given a list of the available Bureau Communautaire de Référence (BCR) biological solid standards. Although solid sampling is attractive, there are major problems. Thus, it is difficult to obtain a homogeneous, representative sample in microgram amounts in order to minimize inorganic matrix effects. The microweighing of samples is difficult and tedious, and the transportation of these microweighed quantities is difficult even when the sample is weighed directly on a boat, platform or cuvette that can be directly inserted into the furnace.

One possible solution to the problem is to use slurries of the biological tissues. Homogenization of the slurry can be achieved in situ by automated ultrasonic agitation and the homogeneous slurry can be immediately pipetted into the graphite furnace using conventional liquid-handling devices such as autosamplers or pipets. According to Miller-Ihli, reliable results can be obtained using as little as 1 mg of finely ground (<500 μm) sample suspended in 1 mL of dilute acid (e.g. 5% HNO₃) or water which contains 0.005% Triton X-100 to aid particle dispersion. Nevertheless, slurry sampling of biological materials is still in its infancy, and more studies will be required before its applicability is firmly established. Slurry sampling seems best suited for powders such as soils, and biological tissues are not powders unless they are freeze-dried and pulverized, in which case many of the advantages of solid sampling may be lost. For example, the reagents used in slurry preparation may lead to contamination. Also, the small mass used in slurry sampling entails a more stringent need for homogeneity than in the case of solid sampling.

4 INDUCTIVELY COUPLED PLASMA ATOMIC EMISSION SPECTROMETRY

4.1 Direct Methods

Direct methods with or without dilution are applicable to the ICPAES and ICPMS analyses of biological fluids provided the analyte concentrations are at least 10 times higher than the detection limit. This is the case for the ICPAES determination of Na, K, Ca, Mg, Ba, Cu, Fe and Zn in serum and urine. The samples are usually diluted with high-purity water or acids by a factor of 5–10 to minimize clogging of the nebulizer by the lipid matter, and the resulting solution is injected into the plasma. Al, Cu and Zn have been determined by dilution of serum with 1.3 M KCl. The use of KCl serves to enhance the Al signal and minimize matrix effects. Sample sizes of >1 mL of both the fluids are usually recommended. It is also possible to minimize both the sample size and dilution factor using an on-line FIA system for the simultaneous determination of Ca, Fe, K, Li, Mg, Na and Zn in 20 μL of a 1:1 aqueous diluted serum. Dilution of serum with Triton X-100 results in fouling of the nebulizer and torch by protein deposits, and therefore is not recommended.

An interesting direct analysis approach involves the electrothermal vaporization (ETV) of microliter volumes of biological fluids in a graphite furnace, cup or rod, or tungsten loop, and the subsequent transportation of the generated aerosol vapor into the inductively coupled plasma (ICP) in a carrier-gas stream. The ETV/ICPAES method requires only 5–10 μL of samples, offers good precision and minimizes matrix effects. The method has been used for the analysis of whole blood, serum, urine and ceruloplasmin. Also, some tissue samples have been dissolved in TMAH, and microliter volumes of the solution have been analyzed by the ETV/ICPAES method.
4.2 Deproteinization

The simultaneous screening of Na, K, Ca, Mg, Fe, Cu and Zn in serum has been achieved by vortex mixing 1-mL sample aliquots with a reagent composed of TCA and HCl (deproteinizing agents), hydroxylamine sulfate (for Fe reduction) and yttrium (internal standard), centrifuging the mixture and aspirating the clear supernatant into the ICP-AES system. A nitric acid deproteinization method has been used for the ICP-AES determination of high levels of Cd (>30 ng mL\(^{-1}\)) and Pb (700 ng mL\(^{-1}\)) in whole blood. As in the case of AAS, some workers have dissolved tissue samples in 5–10% TMAH, and aspirated the resulting solution into the ICP.

4.3 Oxidative Decomposition

Oxidative decomposition by either wet or dry ashing is the most widely used sample preparation method for the ICP-AES analysis of biological materials. Generally, the digestion for multielement analyses would require complete destruction of the organic matrix and decomposition of the inorganic concomitants. Any of the wet or dry decomposition methods used in AAS analyses can be applied. The reagents most commonly used are nitric acid–perchloric acid or aqua regia. The nitric acid–perchloric acid method will destroy most organic matrices and decompose the inorganic constituents. Aqua regia digestion is also effective unless there is concern over volatile analytes such as arsenic.

The sample preparation studies of Dalquist and Knoll and Ward et al. have been the most comprehensive. They evaluated the suitability of dry ashing and wet ashing, with either nitric acid–perchloric acid or nitric acid–hydrogen peroxide, for the ICP-AES determination of 18 elements in serum, bovine liver and muscle tissues. The nitric acid–perchloric acid method had a slight edge over the other two methods. Although nitric acid–perchloric acid requires the use of a perchloric acid fume hood, quantitative recoveries were obtained for all the elements investigated, including potassium. Templeton has summarized selected sample preparation methods that he considers would lead to reliable analysis of biological fluids and tissues by ICP-AES. The information is presented in Table 3. The nitric acid–peroxide digestion procedure proved to be tedious because of the need to add the peroxide dropwise to the cool solution for maximum oxidizing power. The high dilution factors required to give a solution that can be nebulized over several hours of operation without building up fats in the nebulization system is also a distinct limitation for the determination of trace elements.

In recent years, digestion involving mineral acids, especially HNO\(_3\) or HNO\(_3\)–HClO\(_4\) in closed vessels under pressure, and heated thermally or with microwave energy, has become the preferred method. PTFE vessels may not lead to complete decomposition of samples because of temperature and pressure limitations, but quartz vessels which can withstand temperatures up to 300°C at a pressure of 80 bar permit complete destruction of organic matter even without the use of HClO\(_4\). Closed-vessel digestions minimize external

contamination and loss of volatile elements, permit rapid sample decomposition (e.g., 20 min for microwave vs 3 h for conventional hot-plate) and give low analytical blanks. These systems have become increasingly automated and reliable, and are commercially available.

Dry ashing is relatively simple and ideally suited for batch-type procedures. Also, a smaller dilution factor could be employed to improve the sensitivity of some of the trace elements since the solid loading of the dissolved ash is small. However, volatile elements such as arsenic and selenium may be lost if care is not exercised in controlling the ashing temperature. In addition, low recoveries have often been obtained for Al, Cr and Fe.

The ICPAES determination of trace elements (e.g., Cd, Co, Cr, Mn, Ni, Pb, Sn and V) in biological samples requires some form of preconcentration/separation because of inadequate detection limits. It is seldom possible to dissolve the residue resulting from wet or dry ashing without diluting the original analyte concentration. Any preconcentration/separation method chosen should preserve the multielement capabilities of the ICP, should provide a high concentration factor and should minimize matrix effects. These criteria seem to be satisfied mainly by chelating ion-exchange resins, and it is no surprise that the majority of preconcentration/separation procedures are based on these resins. In addition, automation of the preconcentration/separation procedure using flow injection techniques in conjunction with ICPAES measurements has been shown to improve efficiency, sensitivity and selectivity. Recently, on-line preconcentration/separation systems have become available as accessories for spectrometric techniques.

Horváth et al. have comprehensively reviewed the preconcentration and separation techniques for ICPAES and ICPMS. Some selected examples are presented here. Thirteen elements were separated and concentrated from perchloric acid–nitric acid–or perchloric–nitric–sulfuric acid-digested solutions of bovine liver and oyster tissue samples using the Chelex-100 chelating resin in the pH range 4.7–5.5. Only Cd, Cu, Mo, Ni and Zn could be consistently recovered quantitatively in the Chelexed fraction by elution with dilute nitric acid. The As, Sb and Se in an aliquot of the digestate were concentrated, separated and quantitatively recovered as the hydrides, which were introduced into the plasma. Horváth et al. used the poly(dithiocarbamate) chelating resin to preconcentrate and determine simultaneously 10 or more trace elements in urine by ICPAES. They obtained a concentration factor of 125 and were able to reduce the potential interference of alkali and alkaline earth metal ions since the resin showed little affinity for these major elements. Elements such as As, Bi, Sb, Se, Sn and Te were introduced into the plasma as the hydrides. They were also able to speciate Cr(III) and Cr(VI), Se(IV) and Se(VI) and Te(IV) and Te(VI) by carefully adjusting the pH prior to resin complexation. The same approach was extended to the analysis of bone. In the case of serum or bovine liver, the sample was pressure digested with nitric acid–perchloric acid, the digested residue was diluted with water, the pH was appropriately adjusted (e.g., pH 4.5 for Cd, Co, Mo and V and pH 8 for Cu, Fe and Zn), the solution was passed through the poly(dithiocarbamate) resin column, the resin was decomposed using nitric acid–hydrogen peroxide and the digested resin solution was used for the ICPAES analysis. Schramel et al. reported the reliable simultaneous determination of Cu, Mn, Ni, V and Zn in certified reference samples of mussel, bovine liver, milk powder and human hair by an on-line preconcentration of the nitric acid pressure-digested solution at pH 6.5 on an oxine–cellulose microcolumn coupled to the ICP.

4.4 Solid Sampling
Powdered samples of bovine liver have been analyzed by the ETV/ICPAES approach. The sample was micropulverized using the cold brittle fracture technique, 0.5 mg was weighed into a graphite microboat, which was placed on the carbon rod atomizer, the sample was atomized and the aerosol vapor was transported into the ICP for the simultaneous determination of Ca, Cd, Cu, Fe, K, Mg, Na, Pb and Zn. The results agreed with the certified values within ±15%. The analysis of single strands of hair using a direct sample introduction device for Cu and Zn has also been described. The ETV/ICPAES technique is of recent origin, and increased interest in its use for biological analysis is expected. Rapid ETV/ICPAES procedures with as little sample preparation as possible would be useful in hospital and clinical laboratories.

5 INDUCTIVELY COUPLED PLASMA MASS SPECTROMETRY

5.1 Introduction
The biological applications of ICPMS have been reviewed. Few specimens can be analyzed directly. Direct analysis causes problems such as blockage of the pneumatic nebulizer, the central quartz tube of the torch and the sampling orifice due to the high protein content of biological fluids. The problem is especially severe when the dissolved solids content is >0.2%. The high solids content can also cause spectral and matrix interferences. Anions and metals in Groups IA and IIA of the periodic table are the major interferents, and are present
in abundance in biological materials. Therefore, some form of sample preparation mainly to convert the biological specimen into an appropriate solution is required. Depending on analysis requirements and specific interferences encountered, separation and preconcentration steps would also be required during sample preparation. The sample preparation methods used in ICPMS are presented below.

5.2 Dilution

The dilution method has been applied to the analysis of whole blood, serum, urine and milk powder. Dilution is possible in the case of ICPMS because the majority of elements have detection limits below 1 µg L⁻¹. Delves et al. diluted whole blood 25-fold with a diluent composed of ammonia, (NH₄)₂H₂EDTA, NH₄H₂PO₄, Bi and Triton X-100 for the measurement of total Pb concentration and stable Pb isotopic ratios at blood Pb levels >100 µg L⁻¹(1). The ammonia, EDTA and phosphate solutions impart a temporal stability of at least 48 h to the diluted blood solution by maintaining the pH at 8.5 to prevent any precipitation. The use of Bi as the internal standard overcomes the diurnal variations in sensitivity. Addition of Triton X-100 prevents blockage of the nebulizer, improves the wash-out of the sample after the analysis and improves the nebulizer efficiency.

Al, Ba, Bi, Br, Cd, Co, Cs, Cu, Fe, Li, Mg, Mn, Mo, Ni, Pb, Rb, Sn, Sr and Zn have been determined in human serum by a 5- or 10-fold dilution of the sample either with 0.14 M ultrapure nitric acid or with ultrapure water. Internal standards such as Be, In or Tl were used to correct for matrix effects. Uranium in human plasma was determined by a threefold dilution of the sample with a diluent consisting of 1% nitric acid and 25 mg L⁻¹ Eu (internal standard). (1)

Attempts have been made to determine directly the elemental composition of urine either by using a Hilderbrand grid nebulizer, which permits aspiration of concentrated salt solutions or using on-line FIA together with direct injection nebulization. (1) A 3- or 10-fold dilution of the urine sample with water or 1% or 0.14–0.28 M nitric acid has also been used. (22)

Direct, simultaneous determination of 35 elements in CSF by direct introduction of the sample into the ICPMS system has been reported. (1)

The simple direct and dilution methods outlined above have been found to be inadequate for the measurement of elements between 40 and 80 u, especially elements such as As, Cr, Se and V because of spectral interference caused by the formation of polyatomic species such as ¹⁸O³⁵Cl⁺, H¹⁶O³⁵Cl⁺ and ⁴⁰Ar³⁵Cl⁺ by interaction with the NaCl present in serum and urine. Minimization of these interferences requires separation of the analytes from the matrix. Thus, chromatographic methods such as gel filtration, ion chromatography and anion exchange have been used to remove the chloride interference prior to ICPMS determination of total elemental levels or isotopic composition of aqueous dilutions of serum and urine samples. (1) Arsenic has been preconcentrated and separated as the hydride from a 100-fold diluted urine. (1)

5.3 Oxidative Decomposition

The most widely used approach involves wet ashing techniques followed by dissolution and dilution of the residue to a specific volume prior to analysis. Nitric acid is preferred since it produces the fewest polyatomic interferences, in contrast with HClO₄ and H₂SO₄, which introduce polyatomic ions such as ClO⁻ and SO⁻. Although open digestion (e.g. hot-plate) has been used, the current trend is to use microwave digestion since this permits complete decomposition of the sample with nitric acid alone in the majority of cases (see discussion in section 4). The digested residue is dissolved in water or dilute nitric acid, but the final acid concentration should be kept below 10% to minimize corrosion of the metal sampler and skimmer cones. Vanhoe(23) determined 11 elements in various biological materials such as milk powder, wheat flour, rice flour, bovine liver and pig kidney after subjecting 0.3–0.4 g of sample to a two-step microwave digestion with nitric acid. The two-step program was necessary to avoid damage to the decomposition vessels. The digested residue was suitably diluted with ultrapure water prior to analysis. Others have used a single-step hot-plate, pressure bomb or microwave digestion for the multielement analysis of the above samples and also cod liver, shellfish tissue, lobster hepatopancreas, dogfish liver and muscle tissue, human autopsy specimens, rat serum and liver and human whole blood and serum. (1) In general, 100–400 mg tissue samples and 0.5–1-mL blood or serum samples were used in these digestion procedures. Internal standards were used in all cases. Friel et al. used a nitric acid–microwave digestion followed by an open-beaker digestion (hot-plate) with nitric acid–hydrogen peroxide for bovine liver, oyster tissue and animal muscle. (1) The open-beaker digestion was found to be necessary for complete decomposition of the organic matrix and for reduction of the chlorine content which form polyatomic species that interfere with the determination of As, Cr and V. Also, they found a severe loss of sensitivity when imperfectly digested samples were analyzed.

Plantz et al. found it necessary to digest urine samples in nitric acid–perchloric acid, separate the analytes by complexation with bis(carboxymethyl)dithiocarbamate and absorb the complexes on a poly(styrene–divinylbenzene)

5.4 Solid Sampling

There has been considerable interest in recent years in reducing sample preparation times by the use of solid sampling techniques. These approaches are especially useful when the sample is difficult, hazardous or tedious to digest and when contamination errors may arise during conventional dry and wet ashing procedures. One of the most promising approaches to solid sampling is via nebulization of aqueous suspensions of fine powders, termed slurry atomization. The use of a clog-free, high-solids Babington-type nebulizer combined with the high temperature and long residence time of the ICP make it a suitable technique for the slurry analysis of solid samples in which the analytes are present at trace levels. The most critical parameter in slurry atomization is particle size. In general, particles with a diameter larger than 8 µm will not pass through the sample introduction system, reach the plasma and be atomized. The particle size can be reduced to <5 µm by wet grinding 0.25–1 g samples with ZrO beads in a PE bottle on a laboratory shaker for 1–4 h (depending on the sample), and this can result in slurries giving an atomization efficiency equivalent to that of an aqueous solution of the same analyte concentration. Dried milk powder is naturally suited to slurry analysis, as the product is spray-dried during production and has a particle size of <5 µm. Milk powder samples (0.25–1 g) were suspended in 1% Triton X-100 solution to which Mg was added as an internal standard. The slurried suspension was continuously stirred and introduced via a peristaltic pump and a high-solids nebulizer. Excellent results were obtained for Al and Pb. (1) In the case of Pb, the stable isotope ratio was also measured in the slurry using isotope dilution analysis ICPMS technique. Disadvantages with slurry atomization involve sample contamination and sample heterogeneity.

Other solid sample introduction techniques proposed for ICPMS include ETV and laser ablation (LA). The use of LA in ICPMS has been reviewed. (20) Briefly, a highly intense pulsed Nd:YAG laser beam is focused on to the solid sample placed in an enclosed sampling cell. The resulting sample vapor is swept into the plasma using argon. Laser sampling can be used for semiquantitative screening and for obtaining isotopic information. Deposition of vapor on the transfer tube and sampling cell can lead to memory effects.

Application of this technique to biological materials is yet to appear in the literature. The development of procedures for calibration, the availability of appropriate resin column for the reliable measurement of Bi, Co, Cr, Cu, Hg, Mo, Pt and V. (1) The complexation and adsorption separated the trace elements from the easily ionized Na, K and Ca so that matrix effects were insignificant. They could not, however, preconcentrate and separate some of the important metals such as Cd, Pb and Zn under these conditions. Minor changes in the experimental conditions or the complexing agent itself might permit the preconcentration and separation of these metals. Buckley et al. (24) separated and preconcentrated Se as the hydride prior to its determination in several biological materials. Table 4 summarizes selected digestion procedures used in the ICPMS analysis of biological fluids and tissues. (18)

In addition to chemical means, the separation of analytes from the matrix has been accomplished instrumentally, e.g. by ETV. Sample introduction by means of ETV significantly reduces polyatomic interference since the samples are introduced in the absence of any accompanying solvent. An example is the determination of Fe. All the Fe isotopes, $^{54–57}$Fe, suffer severe polyatomic interferences from $^{40}$Ar$^{14}$N, $^{40}$Ar$^{18}$O and $^{40}$Ar$^{16}$OH. These interferences were easily overcome in the determination of Fe in serum by ETV/ICPMS. (1) Branch et al. (25) successfully overcame the chloride interference ($^{40}$Ar$^{35}$Cl$^+$, ArCl$^+$ and ClO$^+$ species) in the determination of As in urine by diluting it 10-fold with 2% HNO$_3$ and by adding as little as 0.032 L min$^{-1}$ (2%) nitrogen to the Ar nebulizer gas.
(corresponding to the high sensitivity of the LA/ICPMS technique), well characterized reference materials and a fundamental understanding of the processes involved in the laser sampling step will undoubtedly promote application of LA/ICPMS to the analysis of biological samples.

5.5 Speciation

Preparation procedures for trace element speciation in biological materials generally involve ‘digestion’ of the organic matrix without changing the species followed by separation and preconcentration of the species prior to determination. The ‘digestion’ method usually involves extraction with organic solvents, and the separation/preconcentration methods are invariably based on chromatographic techniques. The potential of these methods when coupled to ICPMS as a detection system has been highlighted. At present, the most commonly used chromatographic technique is high-performance liquid chromatography (HPLC), possibly because of the simplicity of the interface, the ability to vary the stationary and mobile phases easily to enhance separation and the feasibility of performing the analysis in solution at ambient temperature. Two forms of HPLC have been used, namely ion pairing (both anion and cation pairing) and ion exchange (commonly called ion chromatography). Byrdy and Caruso have outlined some of the problems associated with the HPLC method for ICPMS detection, and have suggested possible approaches to minimize these problems. The major problems associated with sample preparation include (i) clogging of the torch tip and orifices when the total dissolved salt concentration in the mobile phase is >0.2%, which can be minimized by decreasing the buffer concentration, using mixed gas plasmas and using a nitric acid wash between runs, and (ii) high concentrations of organics in the mobile phase may cause carbon deposition on the sampler and skimmer, which will cause plasma instability. This can be alleviated using mixed gas plasmas and cooling the spray chamber.

A few typical examples reviewed by Iyengar et al. are given below. The arsenic species from dogfish muscle were extracted using a methanol–chloroform method, and were then separated into As(III), As(V), monomethylarsenic acid (MMA), dimethylarsenic acid (DMA) and arsenebetaine by ion pairing and ion-exchange HPLC, and were determined on-line by ICPMS. Similar approaches have been used for the speciation of arsenic in urine. Bushee determined methylmercury in albacore tuna by ion chromatography/ICPMS while Beauchemin et al. determined organomercury in dogfish and lobster reference materials after extraction with toluene as chloride and back-extraction into an aqueous medium of cysteine acetate. Tributyl- and dibutyltin have been separated in the lobster hepatopancreas reference material (LUTS-1, National Research Council of Canada) using either a strong cation-exchange resin column or reversed-phase HPLC. Other examples include the detection of gold drug metabolites in human blood serum using HPLC/ICPMS, and cadmium speciation in pig kidney using enzyme digestion and size-exclusion chromatography coupled directly to ICPMS. Another attractive approach which is yet to be explored is supercritical fluid chromatography (SFC) coupled to ICPMS. Use of SFC would permit the analysis of thermally labile, nonvolatile, high-molecular-weight compounds.

5.6 Other Studies

Other studies with ICPMS include isotope ratio measurements in exposure assessment studies and isotope tracer analysis in biokinetics investigations, where the use of radiotracers is undesirable or unavailable. Delves and Campbell used the dilution method described earlier to determine the 208Pb/206Pb isotope ratio in blood in the presence of Pt (194Pt/195Pt ratio) as an internal standard to correct for drift. Janghorbani et al. have extensively dealt with the sample size, sample preparation and separation aspects in connection with the ICPMS measurement of stable isotope ratios in mineral metabolism. The samples include serum, whole blood, urine and stool. Serfass et al. determined the zinc isotope ratio by lyophilizing human plasma and feces samples, dry ashing them at at 480°C, dissolving the ash in 6M HCl and adjusting the pH to 2.5–3.0. Other applications include studies on Se pools, dietary Cu and Zn absorption, Fe incorporation into erythrocytes and clearance of ingested Ni.

6 ANODIC STRIPPING VOLTAMMETRY

6.1 Introduction

Wang and Ostapczuk and Froning have reviewed the application of voltammetry to biological analysis including sample preparation. Among electrochemical techniques, ASV, including differential-pulse anodic stripping voltammetry (DPASV), has been the method of choice for the analysis of biological specimens because of its low cost and excellent sensitivity for the frequently determined metals Cd, Cu, Pb and Zn. Therefore, this section will focus on sample preparation methods used in ASV analysis of biological materials. The reliability of the data generated in the analysis of biological samples using ASV is more dependent on
how well the sample has been decomposed than with atomic spectroscopic techniques. In general, the metal ions to be determined should be released from their binding in the organic matrix and should be presented in the solution state for voltammetric analysis. Incomplete sample destruction results in two major types of matrix interferences. In one type, the matrix concomitants other than the analyte can be electrolytically reduced or oxidized in the applied voltage range giving rise to electrode reactions and hence high background currents (also called faradaic residual current), which can cause problems in the evaluation of the analyte signal. The second type of interference comes from surface-active matrix components which adsorb on the working electrode, inhibit the electrode process (i.e. hinder access of the metal ions to the working electrode) and distort and suppress the voltammetric signal of the metals. Furthermore, the catalysis of hydrogen evolution by the adsorbed organic matter containing nitrogen tends to mask the Cd peak and renders its determination impossible. Needless to say, the limiting factor in ASV analysis of biological materials is the sample preparation step because it is not easy to devise a sample treatment method that would selectively release all the bound trace elements from the sample matrix. In general, solid sampling and direct analysis involving minimal sample pretreatment are out of the question. Some typical examples are presented below.

6.2 Direct Methods

One of the simplest and fastest preparation methods involves the use of Metexchange reagent for the ASV determination of trace elements. The reagent, which is composed of 1.07% CrCl₃ · 6H₂O, 1.43% calcium acetate and 0.0028% Hg(II), rapidly decomplexes the trace metals contained in the sample via an ion-exchange substitution reaction. The reagent has been extensively used in the ASV determination of Pb in whole blood, urine and milk. The main limitations of the method are as follows: (i) the large dilution factor of 30 (0.1 mL blood + 2.9 mL reagent) which prevents reliable measurement of Pb levels below 100 µg L⁻¹; (ii) its high cost; (iii) incomplete removal of organic matter, which usually fouls the electrode by adsorption; and (iv) its ineffectiveness in the presence of competing ligands such as EDTA, which is used as an anticoagulant. Hence the use of Metexchange requires heparin-stabilized blood. Other simple approaches involve the use of low-energy ultraviolet (UV) or high-energy γ-irradiation to decompose the organic matrix and release the bound metals of blood samples. Direct determination of Pb in urine after simple dilution with water leads to erroneous results owing to adsorption of the urine matrix constituents on the electrode surface, complexation of Pb by the surface-active ligands and water-soluble proteins frequently found in urine and the slow oxidation of the mercury film on the electrode by the urine matrix. Bond and Reust directly determined Pb in acidified (0.01 M HCl) urine by adsorptive removal of the organic matter using a Sep-Pak C₁₈ cartridge, an apolar chromatographic medium, followed by filtration through a 0.45-µm filter. The filtration has also been performed in situ at the electrode surface using a permeselective polymeric coating such as cellulose acetate or Nafion. Acid hydrolysis of the urine sample at pH < 0.5 followed by filtration of the solution over a small column of macroreticular resin has also been attempted. Stauber and Florence collected sweat on a 0.45-µm Millipore membrane filter, leached the filter with a supporting electrolyte of NaNO₃–HNO₃ and determined Cd, Cu, Pb and Zn in the leachate by ASV. Also attractive is the use of fused silica to remove interferences by urinary organics.

6.3 Acid Decomposition

As in the case of spectroscopic techniques, acid digestion is the preparation method of choice in ASV. The digestion method chosen should completely destroy the biological matrix and release the metals to be determined; it should not result in loss or contamination of the metal; the digestate (the residue remaining after mineralization) should be dissolved completely in the diluent used; and any excess of the reagents remaining from the digestion should not interfere with the measurement step. Wet digestion procedures with nitric–perchloric–sulfuric acids or digestion with HNO₃ and subsequent HClO₄ treatment have proved to be the most effective for the ASV determination of Cd, Cu, Pb, Tl and Zn in blood, urine, fish and crustacean samples. The same digestion procedure was also effective for As and Sb in urine and blood. In the case of As, the ashed materials were subjected to a reductillation procedure (reduction followed by distillation) to reduce As(V) to As(III) and to separate arsenic from the sample matrix.

Tooth samples have been decomposed with HNO₃–HClO₄ and the residue was taken up in 0.25% HNO₃ for the measurement of Cd, Cu, Pb and Zn. Some studies have used only nitric acid–sulfuric acid, and avoided the use of perchloric acid because of the risk of explosion when organic matter is digested with this acid. However, repeated additions of nitric acid were required to decompose the organic matter completely. Urine, liver and muscle samples were digested in this way for the determination of Cd, Cu, Pb, and Zn. Co, Ni and Se were also measured in the same digestate, but by using
different voltammetric techniques as outlined later. As in the case of the Metalexchange reagent, digestion methods also require high dilutions (up to 50-fold), which do not permit the measurement of metals (e.g. Cd) present at micrograms per liter levels in blood. Pressure digestion with nitric acid alone in a bomb or HPA in quartz vessels at around 300 °C for 3–4 h was found to be sufficient for the ASV analysis of hair, teeth, liver, mussels, herring gull eggs, earthworm, feces and urine for Bi, Cd, Pb, Tl and Zn. Ultrapure acids should be used in order to avoid the high blanks resulting from the attack of the glass and quartz laboratory ware during the digestion process.

6.4 Dry Ashing

Adeloju et al. evaluated three dry ashing procedures for the simultaneous ASV determination of Cd and Pb in bovine liver, and veal tissue samples. The methods considered were (i) direct, (ii) with nitric acid as ashing aid and (iii) with sulfuric acid ashing aid. Methods (i) and (ii) gave less than 90% recovery. Cd and Pb were quantitatively recovered only by method (iii) because the conversion of the metals to their sulfate might have prevented the risk of loss by volatilization. Also, it is advisable to use HCl for the dissolution of the ash since nitric acid undergoes a redox reaction with the mercury drop to give nitrite ion, which interferes with the electrode process. Finally, the dry ashing of biological materials usually gives rise to a carbonaceous residue even when ashing aids are used. This residue will not be dissolved by the HCl used in dissolving the ash. The residue can create problems with ASV analysis. Therefore, it is important to dilute the the sample sufficiently after dissolution of the ash to allow adequate separation of the carbon from the solution by settling. Valetna et al. found LTA in a microwave-excited oxygen plasma to be very effective for the complete destruction of organic matter. They used LTA method for the ASV determination of Cd, Cu and Pb in whole blood and fish.

6.5 Other Voltammetric Techniques

Other voltammetric methods used include cathodic stripping voltammetry for Se in HNO₃–H₂SO₄–HClO₄-digested whole blood and serum, adsorptive stripping voltammetry for Ni in human nails, Co and Ni in blood and Pt in human whole blood and potentiometric stripping voltammetry (PSV) for Hg in urine and Cd and Pb in whole blood and urine. In all cases, the samples were wet ashed in a bomb or HPA, except in the case of Pt where the sample was dry ashed followed by the adsorptive–catalytic reduction of the Pt–formazone complex.

7 X-RAY SPECTROMETRY

7.1 Introduction

Energy dispersive X-ray fluorescence (EDXRF) and particle-induced X-ray emission (PIXE) are the most common X-ray techniques used for elemental screening of biological materials. Both EDXRF and PIXE can usually detect elements at the micrograms per gram (parts per million, ppm) level or a few tenths of 1 ppm. Samples are prepared for EDXRF and PIXE analysis either as thin or as thick targets. A thin film is defined as one in which the sample mass/unit area is <0.1 g cm⁻² and a thick target is one in which the mass of material is sufficient to stop the the projectile beam. For example, the range of a 2.5-MeV proton in a biological matrix is 100μm, corresponding to ~10 mg cm⁻² for material of unit density. Although a thick target presents the maximum amount of sample to the beam, thereby improving sensitivity, calibration is more difficult than with thin samples because of matrix effects. Therefore, thin targets are invariably preferred.

In general, PIXE is two to five times more sensitive than EDXRF and is more suited to the analysis of small sample sizes. However, direct ultratrace analysis is not feasible with either technique because of poor sensitivity, and a preconcentration step is essential to bring the trace metals in biological specimens to detectable levels. Preconcentration is generally effected by air drying, ashing (oven or LTA) or freeze-drying. Since the preconcentrated material is not self-supporting, especially with thin targets, the preconcentration is usually effected on suitable ‘backings’. In general, the backing must consist of low-Z material, should provide minimal contamination and its thickness should be ≤4 μm to minimize the X-ray background and thus to improve sensitivity. The mechanical strength of the backing should be such as to withstand irradiation, handling and sample preparation procedures. Many materials have been used as backings, including thin foils of carbon, collodion, Formvar, Kapton, Mylar, different filters (Millipore, Nuclepore) and others. In addition, the sample is often doped with internal standards such as Ag, Sc, Ti, V, Y or a combination of them to facilitate calibration and to minimize errors due to instrumental fluctuations, sample preparation variations and geometry variations in sample density. The simultaneous use of two or even three internal standards provides a valuable control of the analysis, and, if the internal standards differ significantly in atomic number, such as Sc and Y, assures accuracy of the matrix correction applied. The endogenous concentration of the selected internal standards should be low in the samples. Räisänen et al. have summarized some of the problems encountered in the preparation of thin-film targets.
7.2 Biological Fluids

The sample preparation procedures used for the EDXRF multielement (usually Br, Ca, Cu, Fe, K, Rb, Se and Zn) analysis of plasma and serum have been reviewed. Preparation information on samples other than serum and plasma can be found in a review by Williams. Sample preparation in the case of blood usually involves addition of 50 µL of a 1000 mg L\(^{-1}\) solution of at least two internal standards to 1 mL of serum, plasma or whole blood, vortexing, pipetting 250 µL of the vortexed mixture on to the center of a 4-µm-thick film of Formvar (caution should be exercised in using Formvar as occasional charging problems have been observed), Mylar or polypropylene suspended on a Teflon\(^{®}\) ring that fits into the sample changer of the XRF unit, and drying overnight in a laminar-flow clean-air hood at ambient temperature (air drying) or by placing the sample in an evaporation chamber under vacuum for 1 h. The target prepared in this way ranges in thickness from 5 to 10 mg cm\(^{-2}\), and provides an elemental concentration enhancement factor of 11.3 on average. The concentration factor can be further enhanced by ashing the sample in an oven at 400 °C or in a current of microwave-induced oxygen plasma (LTA), but loss of volatile elements such as Br and Se is a distinct possibility under these conditions.

In the freeze-drying approach, the serum or serum albumin sample is lyophilized for 72 h, the resulting powder is homogenized, 0.1 g of the powder is doped with an aqueous solution of internal standard (e.g. 1 mL of 200 mg L\(^{-1}\) Ag) and 10 µL of the doped solution are pipetted on to a Mylar film mounted on a PE target frame and vacuum dried as above. In some cases, the dried material has been pelletized for the elimination of errors resulting from sample heterogeneity. Some workers recommend a 50% dilution of the sample to minimize background continuum. For example, Rastgar et al. and Maier et al. diluted samples of serum and lavage fluid (collected from the human bronchial alveoli) 50% with an aqueous solution containing two internal standards (Y and V) and air-dried a 20–50-µL aliquot as above for EDXRF analysis, and Sargenti-Mayer et al. determined Pt in plasma and filtered plasma by diluting the sample 50% with 0.5% poly(ethylene glycol) to ensure a better mechanical cohesion of the dried sample film.

Selective enrichment procedures have been used for single-element determinations. For example, the pretreatment steps used for the measurement of Se in serum and whole blood and in IAEA fish soluble certified reference material (CRM) A-6/1975 involved wet digestion followed by coprecipitation with Te, which also served as an internal standard. Pd, Ge and Cr have also served as internal standards for the EDXRF determination of Cu, Pb and Zn in urine, Agarwal et al. prepared a composite solution of 4 mL of urine, 0.5 mL of 3.4 mg L\(^{-1}\) yttrium (internal standard) and 0.5 mL of a suitable standard solution of the elements of interest, preconcentrated the elements by adding the composite to 0.5 g of Chelex-100 resin (sodium form) and mixing for nearly 2 h on a rotating mixer at pH 7, filtered off the solution, dried the resin and placed a portion in a sample holder for analysis.

Räisänen et al. found that when the sample size is small (<30 µL), as in the case of CSF, the usual methods of preparing thin-film targets were not successful for PIXE analysis. They prepared thin, self-supporting CSF films by pipetting 20–40 µL (2–4 drops) of sample into 2-mm holes made in a 125-µm thick Kapton foil and drying at room temperature after the addition of each drop. The holes were made with an Mo spike, as Mo was not measured and did not produce any overlapping peaks. Yttrium (14 mg L\(^{-1}\)) was added to the sample as an internal standard and EDTA (5 µg L\(^{-1}\) of sample) was added to carry and homogenize the ionic components. Reliable data were obtained for Br, Ca, Cu, Fe, K and Zn.

7.3 Tissues

The techniques and problems associated with the preparation of thin biological tissues for XRF and PIXE analysis have been reviewed. Preparation methods used include sliced tissue sections supported on ultrathin polystyrene films, or between Formvar foils, evaporation of homogenates on to suitable backings as in the case of biological fluids, direct irradiation of ashed specimens and self-supporting tissue sections. Elements frequently determined in tissues are the same as in the case of biofluids. Wallin et al. determined Co, Cr, Cu, Fe, Mn, Ni, Pb and Zn in proteins associated with tubulin and microtubules prepared from bovine brain by lyophilizing the sample containing added internal standards of Y and Sc, pressing 8–25 mg of the powder into pellets and mounting them on plastic foils for EDXRF analysis.

Maenhaut et al. prepared human autopsy kidney samples and bovine liver [National Institute of Standards and Technology (NIST) Standard Reference Material (SRM) 1577] for PIXE analysis as follows. The samples were freeze-dried, pulverized and homogenized. A 0.1–0.2-g amount of the homogenate was then doped with an aqueous solution of Ag as an internal standard and prepared for PIXE analysis on a Mylar backing as described for serum above. The concentration factor and hence the sensitivity can be enhanced by dry ashing the homogenate prior to doping; the same group prepared bovine liver (NIST SRM 1577a), animal muscle (BCR CRM 63) and milk powder (IAEA CRM H4) by
microwave digestion of the sample (0.1–0.2 g) with nitric acid (1 mL/0.1 g) containing 9 mg L\textsuperscript{−1} Y as internal standard, pipetting 10 µL of the digestate on to a 1.5-µm-thick polycarbonate film mounted on a 25-mm diameter PE target frame and drying the target in a vacuum desiccator\textsuperscript{(1)} Gunther et al.\textsuperscript{(34)} on the other hand, digested the bovine liver sample with nitric acid using a hot-plate, dissolved the residue in 5% HNO\textsubscript{3}, spiked a 450-µL aliquot with 50 µL of 25 mg L\textsuperscript{−1} Ga as internal standard, pipetted 20 µL of this mixture on to a quartz-glass carrier, evaporated to dryness using an infrared (IR) lamp and analyzed the residue by total reflection XRF. The digestion procedure, however, resulted in loss of Br with recoveries of only 8–26%. For the EDXRF analysis of Pb in human teeth, 100–200-µg samples were dissolved in 50 µL of 50% HNO\textsubscript{3} containing 5 mg L\textsuperscript{−1} Y and 5 µL of this solution were deposited on a 4-µm thick polypropylene film and dried at room temperature.

Bloch et al. measured the Pb level of children’s teeth in situ by EDXRF with a pencil beam of γ-rays from a \textsuperscript{57}Co source. PIXE analysis of deciduous molar enamel for Pb was carried out by powdering the dried teeth in a mechanical mill, separating the enamel from dentine by a flotation method and compressing the enamel powder into pellets 5 mm in diameter and 0.5–2 mm thick. The crown, root and jaw bone located around and underneath each tooth of a 97-year-old female cadaver were similarly analyzed for Br, Cu, Fe, Mo, Pb, Sr and Zn by powdering and pelletizing each sample and attaching the pellets either with 20 µL of a 15% ethanolic solution of polyvinylpyrrolidone or Krazy glue to Kapon films.\textsuperscript{(1)} Williams has summarized the application of PIXE to the trace element analysis of hair.\textsuperscript{(31)}

Renan et al. preferred the use of ‘thick’ liver samples for PIXE analysis.\textsuperscript{(1)} The use of ‘thick’ samples simplifies preparation techniques, minimizes contamination, enhances sensitivity, reduces target heating and minimizes selective volatilization of labile analytes such as Br. However, literature studies with thick samples are not extensive, possibly because of matrix effects. They also prepared murine liver sample for PIXE analysis by homogenizing, lyophilizing at −45 °C for 8 h, powdering, compressing the powder into a disk (13 mm diameter, 2 mm thickness) and mounting it on a Perspex holder for irradiation.

8 NEUTRON ACTIVATION ANALYSIS

According to Heydorn,\textsuperscript{(35)} NAA is becoming less and less popular because the geographical separation between an NAA laboratory (with its associated nuclear reactor) and a hospital prevents the routine use of this technique in a clinical setting. Apart from this problem of inaccessibility, the instrumentation is very expensive and requires highly skilled professionals to carry out the analysis. Also, its sensitivity is poor for some of the key elements such as Pb. Hence NAA cannot be considered as a routine technique. It may serve as a reference method because of its insensitivity to contamination by stable elements after irradiation, minimal handling required prior to irradiation and the absence of a blank value. However, it is important to ensure that no contamination of the sample occurs before irradiation. Reference laboratories such as NIST are well versed in NAA sample preparation methods, and the IAEA has dealt with the practical aspects of NAA in a technical document.\textsuperscript{(36)}

A brief outline mostly based on this document is given below.

The high sensitivity of NAA for many elements and the necessity to use optimally the space available within the irradiation container call for the use of small sample sizes in the range 50–500 mg. Clearly, sample homogeneity is critical. Samples in dry form are preferred for irradiation in order to avoid potential radiolysis problems and the attendant precautions. However, liquids and solids containing moisture can be irradiated when irradiations last only a few seconds and where irradiation ports and cooling facilities are available.

In NAA, samples have to be irradiated in a container. The most commonly used container materials are PE (both conventional PE and linear PE) and quartz. When the flux needs to be modified, the container can be lined with graphite. PE is suitable for most purposes. It is inexpensive and available in high purity, can be fabricated in various forms and sizes, can be efficiently cleaned with HNO\textsubscript{3} and can be easily sealed. For most applications, it is sufficient to use a snap-on lid. Capsules cut from PE microcentrifuge tubes will hold 100 mg of sample powder and can be conveniently bundled into a rabbit. PE screw-capped bottles are useful for large samples or for containing numerous samples.

The major disadvantage of PE is that volatile elements such as Hg and halogens diffuse through it during long irradiations, and in these situations samples have to be irradiated in quartz containers. High-purity quartz should be used since mineral quartz is activated strongly, and it is difficult to transfer biological materials to a pure capsule for counting. Graphite containers are preferred when a pneumatic transfer system (e.g. cyclic determinations) is used for irradiation in a very high neutron flux. Graphite is obtainable in high purity, but is very expensive. Therefore, it is used only in special cases.

All major elements in the human body except P can be directly determined in vivo using prompt γ neutron activation analysis (PGNAA). This information allows the calculation of the body composition with
the exception of trace elements and P, and for this purpose PGNAA has been accepted as a reference method. In in vitro biological trace element analysis, direct determination [referred to as instrumental neutron activation analysis (INAA)] is seldom possible because of interferences. The interfering activities have to be eliminated by radiochemical separation [radiochemical neutron activation analysis (RNAA)]. This involves addition of a suitable amount of inactive carrier of the analyte to the sample to control and minimize losses, irradiation, decomposition of the irradiated sample using nitric, perchloric or sulfuric acid, and radiochemical separation. Complete isolation of the analyte is not required, and several group separation schemes have been developed. Particularly simple separations may be effected by adsorption on activated carbon or by elimination of only $^{24}$Na from the sample.

Sample Preparation for Environmental Analysis in Solids (Soils, Sediments, and Sludges)

David Eugene Kimbrough
Castaic Lake Water Agency, Santa Clarita, USA

1 Introduction
There are generally two parts to chemical analysis, sample preparation and instrumental analysis. There is one overriding consideration in selecting a sample preparation procedure: the data quality objectives of the final data user. Samples are analyzed in order to answer questions that will impact human health and the environment and different levels of accuracy and precision are needed to answer different questions.

Data users must consider the issue of data comparability. If the analytical results are to be compared to other sets of results, there is the possibility that the results may produce significant differences from those generated previously or expected. One possible explanation is that a different analytical method was used. For this reason researchers and especially regulatory agencies have traditionally used standardized (a.k.a. prescriptive or “cook-book”) methods to eliminate this possibility. These may be used by either standard-setting organizations (e.g., American Public Health Association (APHA), American Water Works Association (AWWA), Water Environment Federation (WEF), American Society for Testing and Materials (ASTM)) or regulatory agencies (United States Environmental Protection Agency (USEPA), United States Occupational Safety and Health Administration (USOSHA)). In a great many cases the use of certain sample preparation procedures is a statutory, regulatory, or policy requirement.

However, because new analytes of environmental concern are being added constantly, and new or radically improved analytical instruments and techniques are being introduced, the ability of regulatory agencies to keep pace with these changes and incorporate the most recent procedures is severely limited. Likewise, standard-setting organizations are generally quite conservative about the introduction of new techniques and do not incorporate the latest techniques very quickly. As a result standardized methods tend to be behind the state of the art and nowhere near the cutting edge. Thus the data user must also consider the strictly scientific needs, and ask whether a given procedure can analyze the analytes of interest in digestion is the most common sample preparation for elemental analysis. The acid must be aggressive enough to break the bonds between the analyte and the matrix and it must yield a form of the element soluble in the acid. NOCs are generally extracted from the sample matrix by organic solvents. The extraction solvent must be more soluble to the analyte than the sample matrix and the solvent must be able to penetrate into the sample matrix in order to solubilize the analyte. Thus the correct selection of acids and extraction solvents is the key to successful extraction.
the matrix of interest over the range of concentrations of interest at the appropriate cost. For solids (soils, sludge, sediments, solid wastes, etc.) by far the most commonly used set of standardized methods is SW-846 prepared by the USEPA Office of Solid Waste for work associated with the Resource Conservation and Recovery Act (RCRA) and the Comprehensive Emergency Response Compensation, and Liability Act (CERCLA). While this document was only intended to be a guide and not a required set of methods, in many situations it has become so. As a result, in many situations these methods are used for the sake of data comparability or simple conservatism.

2 MATRIX

The term “sample matrix” is one that is often used but rarely discussed. The simplest explanation is that the sample matrix is the portion of the sample that is not of interest, it is all of the nontarget elements and compounds. It is also usually (but not always, especially with industrial wastes) the vast majority of the mass of the sample. The sample matrix often “interferes” with the extraction or digestion of target analytes and so special steps are often needed to remove or mitigate these interferences. Similar matrices should have similar effects on the same analysis. In many standard methods matrices are often defined such as “soil”, “solids”, or “others”. It is not possible to predefine matrices in this fashion.

A matrix must actually be defined by the effect it has on an analysis. For example, in drinking water, the amount of calcium in the water has no effect on the analysis of volatile organic compounds (VOCs) so a very hard water and a very soft water are both the same matrix for VOC analysis. In contrast, calcium has a strong effect on the analysis of barium by flame atomic absorption spectroscopy (FAAS), and thus a very hard drinking water would be a different matrix from a very soft water. Thus two waters are the same matrix for one analysis and two different matrices for another. In a similar fashion, how a sample matrix interacts with a sample preparation procedure is determined by the effect the matrix has on the final results, not on its physical state or appearance. Two tars might be physically very similar but one that is high in sulfur will be more difficult to analyze for barium than one that is low in sulfur.

There are many ways to group analytes of environmental interest. However, from a sample preparation point of view there are really only two types of analytes. Volatile analytes, those that will readily leave the solid phase of the sample and enter the gaseous phase of the sample container (generally the head space), the atmosphere, or some other equally useless space, generally have no sample preparation at all as any manipulation of the sample will result in loss of the analyte. Non-volatile analytes are those, such as metals and pesticides, which do not leave the solid phase for the air.

3 PHYSICAL PREPARATION

Solid samples can contain a wide ranges of moisture and must often be dried prior to analysis. This is done for a variety of reasons: one is so that comparisons between samples are more realistic and not skewed by differences in moisture content. Drying can also make other sample preparation procedures easier, such as milling and sieving. Finally, some analytical procedures are sensitive to moisture content and so by removing moisture the samples are more similar to the calibration standards. Some samples such as soils, sediments, and solids can be dried simply by placing them in drying ovens at 105 °C for 24 h.

Milling solid samples is often performed in order to achieve a more uniform particle size. Some analytical techniques are very sensitive to particle-size effects and milling minimizes this problem; this applies to X-ray fluorescence and neutron activation in particular. Particle-size reduction also increases the surface to volume ratio which is important for effective extraction procedures (see below). Milling also make sieving easier. Sieving is used to remove portions of solid samples that are extraneous, such as rocks, wood, and debris. It also complements milling by removing larger particles that need further milling. Milling and sieving also have the effect of homogenizing the sample, especially with samples with a heterogeneous distribution of analytes.

4 ACID DIGESTIONS FOR ELEMENTS

These procedures remove the elements of interest from the sample matrix, transfer them to liquid matrix, and then the liquid extract is analyzed by instruments and compared to other liquid standards. The most common approach is the use of hot acids to destroy chemical and physical bonds between the elements of interest and the matrix and to convert those elements into water-soluble forms, often leaving the bulk of nontarget elements, especially siliceous materials, as solids that can be filtered out.

In selecting an acid digestion procedure, two important factors need to be considered: is the acid (or acid mixture) aggressive enough to break the bonds between the analyte and the matrix, and will the element be soluble in the acid? For example, there are a number of acid digestion...
procedures that use hot nitric acid. If copper oxide were bound to the surface of a carbonaceous particle, when exposed to hot nitric acid a significant portion of the carbon on the surface of the particle will be mineralized to CO₂, thus freeing the copper atoms. The copper will be converted to copper nitrate which is quite soluble in nitric acid and in water. In contrast, consider antimony trioxide in an oil. Nitric acid is not strong enough to break up the oil’s molecular bonds. Further, the oil will float on top of the acid so that the nitric acid would only interact with the surface of the oil. Likewise, if the sample is composed of a small number of very large units, i.e. it is very “lumpy”, then the acids can only attack the surface and will not be able to penetrate the sample matrix. It is here that milling and sieving are very important.

A wide variety of oxidants can be used: nitric acid, hydrochloric acid, sulfuric acid, perchloric acid, hydrofluoric acid, potassium permanganate, and hydrogen peroxide to name the more common. The most common techniques are designated in SW-846 as methods 3050, 3051, and 3031. In addition, the USEPA has a parallel set of methods for its contract laboratory program (CLP). In this set it has used an acid digestion procedure included in the inductively coupled plasma mass spectrometer (ICPMS) procedure 6020 (CLP). 3050 is in fact three different methods for non-oily samples using a hotplate as the heating source. One version is a simple nitric acid digestion which is nearly identical to the ASTM method 9.3.4 using 2 g of sample digested in concentrated nitric acid. A second version is a sequential digestion of 2 g of sample in nitric acid and then hydrochloric acid. In the third method 2 g of sample is digested in a 4:1 mixture of hydrochloric to nitric acid (similar to aqua regia), followed by a hot hydrochloric acid rinse, and then the filtered residue is digested again in hot hydrochloric acid and filtered again (all three of these filtrates are combined). Method 3051 is a simple nitric acid digestion using a microwave heating technique. Method 6020 (CLP) uses dilute acid (2 + 3) nitric acid and then dilute (1 + 4) hydrochloric acid heating on a hot plate. There are many other methods but they are not very different from these and these are the most commonly used.

In examining these procedures, it is useful to look at a limited number of elements and see how they interact. In one published study three of these methods were compared on a variety of pure compounds, soils, and solid waste samples by inductively coupled plasma atomic emission spectroscopy (ICPAES). The linear range of a procedure is the range of quantities where there is a linear correlation between the actual quantity in the sample and the measured quantity. Each analytical procedure has upper and lower limits beyond which accurate and reproducible results cannot be obtained.

As can be seen on Table 1, where 1 µg (method 6020) or 2 µg (the others) of pure compounds were digested, not only do different elements have different linear ranges for different methods, the different salts of the same element can behave quite differently. Table 2 shows the results of the same methods on real-world soil and solid-waste samples. The same patterns are observed. The

All results in mg kg⁻¹.
Method 6020 (CLP) consistently got lower results for almost all elements and compounds in all matrices. This is no doubt because the digestion procedure is not aggressive using diluted acids in sequence and it was not effective at breaking apart the sample matrix. The plain nitric acid consistently solubilized more lead in all matrices than any of the other methods. This is because nitric acid reacts with lead to form lead nitrate with is extremely soluble in water and nitric acid. In contrast, this method solubilized none of the antimony in any of the matrices. Antimony reacts with nitric acid to form Sb$_2$O$_5$, which is very insoluble in either nitric acid or water. Likewise silver reacts with nitric acid to form silver nitrate which is very soluble in water but has very limited solubility in nitric acid.

The two versions of 3050 that used a mixture of nitric acid and hydrochloric acid solubilized less lead than the plain nitric version because the hydrochloric acid reacts with the lead to form lead chloride which is not as soluble in water and hydrochloric acid than lead nitrate is in water and nitric acid. On the other hand while Sb$_2$O$_5$ is also produced by these two versions Sb$_2$O$_5$ reacts with hydrochloric acid to form Sb$_2$O$_5$Cl which is very soluble in hydrochloric acid. Similarly, silver reacts with the hydrochloric acid to form AgCl. The amount of both of these chlorides that can be solubilized is determined by the amount of chloride ion in solution. Thus the more hydrochloric acid is used, the more of these elements is solubilized. This can be seen in looking at the methods from least to most hydrochloric acid. The greater aggressiveness of the aqua regia procedure can be seen in it’s efficiency in attacking the elemental pure compounds (Table 1) which are more resistant than the other molecular forms. When hydrochloric and nitric acids are added together a number of other reactive compounds are formed, including NOCl and Cl$_2$, giving additional aggressive qualities. These are by no means the only acid digestion procedures available but they are illustrative of the factors to consider in selecting an acid digestion procedure.

The aqua regia version of Method 3050 has one advantage over the other versions. It requires that the residue in the filter paper be re-digested. Table 3 shows how much analyte (total mass in milligrams) can be left in residue in the filter paper or in precipitate at the bottom of the filtrate. Barium, silver, and lead are the most conspicuous elements in the secondary filtrate (for reasons discussed above) and precipitate but other elements can be found there as well. The other elements are likely co-precipitated, becoming entrained in the precipitate of other elements.

There are a number of methods for heating the acids in these procedures. The most commonly used method is a

All results in mg.
SOLVENT EXTRACTIONS FOR NONVOLATILE ORGANIC COMPOUNDS

Samples to be analyzed for VOCs must not be manipulated in any way as this will result in the volatilization of the analytes of interest. The instrumental procedures generally analyze the sample directly without any preparation. The only precautions are that the samples should be refrigerated at 4°C or lower.

NOCs on the other hand must be extracted from the sample matrix in order to analyzed. The most common approach is to extract the analytes of interest from some liquid solvent. The problem of matching extraction solvents to sample matrix and analyte is similar to that of the acid digestion procedures. The analyte must be more soluble in the extraction solvent than in the sample matrix and the solvent must be able to penetrate into the sample matrix in order to solubilize the analyte. It is very common to concentrate the analytes after extraction to increase the ability of the instrument to measure the analytes. This can be combined with cleanup procedures to remove interfering compounds or cleanup can occur separately.

It is very common to lump different sample matrices together into pre-defined groups as “soils” and “solids”. However the effect of the matrix on solvent extractions depends on the polarity of the matrix, the solvent, and the analyte. Using soils as an example, they contain an inorganic portion made up of very polar oxides of silicon, aluminum, iron, etc. and an organic portion made up of decomposed plant material referred to as humic substances. Humic substances can range from very polar to very nonpolar, even in the sample soil particle. A soil can consist of pockets of very low polarity in a very polar particles or the exact opposite depending on the ratio of organic to inorganic materials and the nature of the humic substances. It would be extremely naive to assume that two such different matrices would have the same impact on the extraction of a given compound simply because they are both “soils”. These principles are true for other sample types.

The polarity of the analyte of interest also impacts the extraction. Very nonpolar compounds such as PCBs must be extracted with nonpolar solvents such as hexane, just as very polar compounds like acidic herbicides must extracted with polar solvents. However, using PCB-contaminated soils as an example, the PCBs, being nonpolar, are likely to be found in the least polar portions of the soil particles. If the soil particle is mainly polar then a very nonpolar solvent such as hexane will have a hard time penetrating the polar portions of the soil to reach the portions containing the PCBs. Combining more polar and less polar solvents can overcome this problem, such as combining hexane and propanone (acetone).

These solvents rarely extract only the analyte of interest; they often extract other organic materials, for example nonpolar humic substances in hexane. Sometimes these materials can interfere with the analytical process either by physically obstructing some part of the instrumentation or by being mistaken by a detector as an analyte. Humic substances can build on the surface of an electron-capture detector (ECD) forming a plaque that causes severe drift. Other substances can be extracted and interfere with other tests. For this reason, whenever possible, cleanup procedures are used.

USEPA’s SW-846 lists a variety of methods for the extraction of different organic compounds from solids of various sorts. As with the acid digestions, there may be legal requirements for the use of these methods or they may be used simply for data comparability or to remain consistent with previous practice. It is not possible to review all possible sample extraction procedures or even those in SW-846 but it is helpful to examine a particular method and see all of the impacts of the above-mentioned variables.

For the analysis of PCBs in solids there are two accepted methods. Method 3540 uses 10 g of sample mixed with 10 g of anhydrous sodium sulfate. The mixture is placed in an extraction thimble (or glasswool) and the thimble is placed in a Soxhlet extractor. A round-bottomed flask, containing 300 mL of the extraction solvents and boiling chips, is attached to the Soxhlet extractor. The flask is heated just to boiling for 16–24 h. The solvent vapor rises from the flask into the condenser. The condensed solvent falls from the condenser into the extraction thimble. The sample and thimble are eventually soaked in the solvent. When a fixed volume of solvent has been collected in the
extractor, it is siphoned back into the boiling flask and the process begins again.

Method 3550 uses 30 g of sample placed in a 400 mL closed beaker. A 100 mL volume of extraction solvent is added and the mixture is sonicated for 3 min with the output control knob set at 10, with the mode switch on “Pulse” and the percent duty cycle set at 50%. After the sonication is complete, the solvent is either filtered or decanted. This step is repeated two or more times, after which the three extracts are combined. The solvent may be heated or left at ambient temperature.

The recommended extraction solvents for both methods are dichloromethane (methylene chloride), 1 + 1 hexane–propanone (acetone) and 9 + 1 toluene–methanol, although this last mixture is rarely used. In practice, four other extraction solvent systems have been used, 1 + 1 dichloromethane–propanone, 1 + 1 dichloromethane–hexane, straight hexane or trimethylpentane (isooctane).

In order to use an ECD, all of the dichloromethane must be removed as a solvent and exchanged with a more suitable solvent, usually hexane. The extract is concentrated to about 10 mL using a Kuderna–Danish concentrator and then 50 mL of hexane are added. The solution is heated until all of the dichloromethane is boiled off and the remaining hexane is brought to volume with more hexane.

There is only one approved cleanup procedure for PCB in hexane extract. However many other USEPA approved methods for other analytes are often used for PCBs.

- Method 3610: This method is intended for the removal of interfering phthalate esters and nitrosamines. The exchanged hexane extract is concentrated to 2 mL and added to the top of a preconditioned alumina column. The PCBs are then eluted from the column.
- Method 3620: The exchanged hexane is concentrated to 2 mL and added to a Florisil column. The PCBs are eluted from the column using 6% diethyl ether in hexane. The solvents are reconcentrated and exchanged back to hexane.
- Method 3630: This method is intended for polycyclic aromatic hydrocarbons (PAHs) or derivatized phenols. The extract is exchanged to cyclohexane and placed on the top of a column preconditioned with pentane. PAHs are eluted using dichloromethane–pentane (2 + 3) and then reconcentrated and exchanged to hexane.
- Method 3640: The extract must be dissolved in dichloromethane. It is passed through a gel permeation column and collected in a flask, reconcentrated and exchanged to hexane. The retention time for PCBs is determined by using methoxychlor as a surrogate. It elutes after the phthalates and before perylene and elemental sulfur. There is a 50% loss in the cleanup process for which the analyst is expected to make a correction.
- Method 3665: A 1–2-mL volume of the exchanged hexane is mixed with 5 mL of 1 + 1 sulfuric acid in a tightly sealed container. The phases are allowed to separate and the hexane is transferred into a clean 10 mL vial. The sulfuric acid is washed again with hexane and collected in the same 10 mL vial. Finally, the hexane is concentrated back to its original volume.

Table 4 shows the results of the interlaboratory study where 129 accredited hazardous materials laboratories analyzed five soils spiked with Aroclor 1260 (11–14). As can be seen, the Soxhlet extraction procedure is more efficient at extracting PCBs from the test soils. This is because the solvent was heated, the solvent that is presented to the sample is never saturated, and the extraction period is a great deal longer. The differences are most pronounced at higher concentrations where the extraction solvent has the greatest challenge. Table 5 shows how different solvents performed in the same study. The two nonpolar solvents (hexane and trimethylpentane) extracted significantly less PCBs than the more polar solvents. Given the high solubility of PCBs in hexane it must be concluded that these solvents were not able to penetrate the more polar soil matrix.

Table 6 presents the results for different cleanup procedures. There is little difference between the results from the laboratories which did not clean up, those that used the Florisil cleanup procedure, and those that use the sulfuric acid for the three higher concentration samples. However, for the sample spiked with 0.1 mg kg\(^{-1}\) of PCB there is a very significant difference. Humic materials are extracted from the soils and are creating a positive interference of little more than 0.1 mg kg\(^{-1}\). At the higher

As is also quite evident, the use of the wrong cleanup procedure is as bad as not using any cleanup procedure, if not worse. The laboratories that used alumina column cleanup consistently got lower recoveries at all concentrations than any of the other methods. At the critical concentration of 0.1 mg kg\(^{-1}\), neither the gel permeation nor the sulfuric acid cleanup procedures performed as well on average as did the Florisil column procedure.

6 CONCLUSIONS AND FUTURE TRENDS

As should be evident, the sample preparation procedures are both an absolutely critical component of analytical analysis and one that can be very complex. The strengths and limitations of prescriptive standardized methods are quite evident here. These methods can be very effective when they are well designed. However, subtle differences in the chemistry of acid cocktails, extraction solvents, or cleanup columns can cause serious errors in analysis and it can be difficult to exploit these subtleties when trying to adhere to prescriptive methods. For this reason many regulators and analysts have proposed “method streamlining” and “performance based methods systems”. Method streamlining allows laboratories under regulatory constraints to use standardized methods
to modify these methods provided they demonstrate equal or greater efficiency. Performance-based methods systems would do away with any reference to standardized methods and simply allow the analyst to demonstrate that the data quality objectives of the data user are being met. How far these two initiatives will proceed has not yet been determined.

The reliability of results obtained from chemical analysis of environmental samples is related to the sample collection and preparation techniques. A succession of stages is required to obtain a result that is both accurate and representative of the initial material. The task begins by taking the appropriate precautions during collection of the liquid and solid samples, and during their later shipment to the laboratory. The environmental conditions in the laboratory where the sample will be prepared are important, as is the quality of the apparatus, containers, glassware, and reagents that are usually used. The preparation of solid waste samples requires the selection of appropriate digestion procedures, apparatus that is of high enough quality to resist the aggressiveness of some inorganic acids, and convenient systems of security for the procedures that are carried out. The information produced by the laboratory should have a high degree of reliability. For this reason, the procedures used usually permit the results obtained to be guaranteed. The more important procedures include the use of certified reference materials (CRM) and participation in interlaboratory programs. Some organizations, for example the United States Environmental Protection Agency (USEPA), have developed and distributed procedures for environmental sample preparation, which are used by many laboratories as normalized methods of reference.

1 INTRODUCTION

The sample preparation techniques and the sample collection processes are closely related to the accuracy and representativeness of the final results for the material being studied. This is because the values obtained in the analysis of this material depend fundamentally on the sample characteristics and the chemical procedures used. Sample collection is the first and most fundamental of all the stages within the analysis process for environmental materials, since the utility of the final results will depend on the representativeness of this initial collection. Very careful handling is essential during the sample collection process to avoid significant alterations in composition. Sample integrity must be ensured from collection up to production of the final report. Nevertheless, complete
stability of all the sample components is impossible, especially in domestic and industrial residual waters, since in the best case the conservation techniques can only delay the chemical and biological changes that inevitably take place after collection. On the other hand, sample containers can introduce errors in the measurement of some metals, as a consequence of container wall leaching and/or concentration decreases due to adsorption. For this reason, the samples collected in the field should be kept in borosilicate glass containers or in plastic containers, such as polyethylene, polypropylene or polytetrafluoroethylene (PTFE). Unfortunately, glass containers can be broken during transport or handling and the PTFE containers are very expensive thus polyethylene and polypropylene containers are preferred.

Special care should be taken regarding the working conditions in the laboratory, although a clean and well-arranged workplace and a supply of reagents and solutions of the appropriate quality are the basic requirements for good work, particularly with soil samples, sediment and polluted waters. Conditions in the laboratory should be more stringent when analysis of pure waters or precipitation waters is required, and extreme care should be taken with environmental air quality, material cleaning and reagent quality. Clean benches that use high-efficiency particulate air (HEPA) filters are advisable for handling this type of sample. Fume hoods should be used when the samples require an energetic process of decomposition by means of inorganic acids, and stainless steel or polyvinyl chloride (PVC) hoods when using perchloric acid. The glassware should be mainly made of borosilicate and should be produced according to the Deutsches Institut für Normung (DIN) and/or the International Standardization Organization (ISO) standards. The reagent quality should be at least of an analytical degree according to specifications of the American Chemical Society (ACS). The water quality should conform to the categories of the American Society for Testing and Materials (ASTM).

Pure water collected in the field does not usually require an initial treatment, but if sensitive methods are used for analysis, an evaporation concentration may be required in some cases. The decomposition of solid samples by open digestion procedures is frequently troublesome, and analytical errors are possible, since some elements could be lost or suffer contamination due to the matrix and reagents used. However, these procedures have the advantage of destroying the matrix, thus creating safe homogeneity and also eliminating some of the interferences present in the original sample. The choice of an appropriate procedure is difficult, because if the original sample is diluted to avoid high concentrations of dissolved solids, many elements cannot be determined.

It is also necessary to keep in mind that the information obtained in a chemical analysis laboratory usually plays a key part in social or economic decisions. For this reason, the accuracy and the precision of the results obtained should be such that they generate a high degree of reliability and recognition. Therefore the frequency of instrument calibration, the maintenance of equipment, the glassware quality and the reagent quality should be among the most important considerations of the laboratory. At present, one of the most widely used procedures to assure the quality of the results is the use of CRM that have a matrix very similar to the samples being analyzed. The National Institute of Standards and Technology (NIST) and the Bureau Communautaire de Référence (BCR) are the main suppliers of these materials.

2 SAMPLING

The sampling stage is considered one of the most important in the analysis of samples, since the representativeness of their results will depend upon the way they were collected. The objective of the sample collection is to obtain a material portion whose volume is such that it can be easily transported and analysed in the laboratory, and will accurately represent the material from which it was drawn. The sample obtained during the collection phase should not deteriorate or become contaminated before arriving at the laboratory. Any of the components of interest that are present in the sample are at parts per million concentration levels and even lower. It is possible that these may alter completely or partially if the collection is faulty, or if the person who collects the sample doesn’t take the necessary precautions for conservation. The collection should be carried out carefully with the purpose of guaranteeing an analytical result that will faithfully represent the real composition.

The details of sample collection vary according to the local conditions, so recommendations that have universal application cannot be specified. Several systems have been proposed in the literature. Startin and Lansdown present a system for the collection and treatment of wastewater from highways and paved areas. Robinson et al. describe operational experiences on the collection, treatment and distribution of contaminated solutions that are generated in landfills due to the rotting of enormous quantities of waste. Blommaert et al. present a study about the uncertainties that can hinder the representativeness of the sampling and correct interpretation of the data obtained in a complex waste processing installation. Lohani and Ko present a general approach to determine the sample size and the number of samples in solid waste sampling. The
Department of Energy (DOE) and the USEPA consider the screening methods to be of great benefit in quickly and efficiently studying large numbers of highly polluted places that present a serious risk to inhabitants. Wise and Guerin\(^{(7)}\) show the utility of the screening methods as a technique for direct sampling. They discuss the advantages of a direct sampling method in which an analyte is introduced directly from the sample into a mass spectrometer. Olsen et al.\(^{(8)}\) propose stripping analysis as a field method to give quick, economic and reliable results in the determination of Cr, Cd, Zn, Cu and Pb in sediments.

2.1 Water Sample Collection

Water sample collection varies depending on the collection source. For domestic water systems, the sample should run down through the pipe to ensure its representativeness. When a water sample collected from a river is analyzed it is necessary to keep in mind that the concentrations of the elements under study will vary according to the depth, the stream speed, the distance from the bank and the width of the river. When sample collection is carried out in deep bodies of water it should be remembered that at depths larger than 5 m there is a tendency towards thermal and chemical stratification of the water. This is why the site and the position of the sampling should be registered exactly to obtain representative samples during the sampling period. This is not a problem for sample collection in waters with a depth less than 5 m, since the waters mix by the action of the wind. In lakes and swamps, besides the stratification problem, variations due to natural causes such as the quantity of rainfall, drainage and wind are also present.

In seawater samples the main problem is to prevent sample deterioration between collection and analysis. This is carried out in two steps. First, by filtering the sample through 0.2 \(\mu\)m or 0.45 \(\mu\)m membrane filters for quick separation of the suspended particulate material, and later by acidification of the sample to a pH around 1 to avoid adsorption by the container walls.\(^{(9,10)}\) For certain components, the place where the sample is drawn from is very important;\(^{(11)}\) excessively turbulent areas should be avoided to prevent the loss of volatile substances. In general, the samples are collected under the surface, from calm areas, keeping in mind the tests or analyses that will be carried out or the utility that the final results will have.

2.2 Water Sample Handling

Contamination of the sampling apparatus can produce serious errors during collection and storage of the samples, due to inappropriate cleaning of the apparatus. Several types of pollutants are caused by the material from which the sampling apparatus is built. For example, PVC can contribute Zn, Fe, Sb, and Cu; cellulose filters Cu, Ni, Zn, P, K, etc. and plastic tips Cu, Fe, Zn, Cd, Ni. All this contamination can be minimized by washing the material five times or more with distilled water, or allowing it to soak for two days in 5 N HCL and then rinsing it with ultrapure water. The acidity of the sample, the time that it is in contact with the container, and the presence of complex agents and dissolved active carbon all determine the adsorption of metals on the walls of the container. Table 1 summarizes the requirements for sample collection and handling. The blank used during the analysis is essential to assure the results, since this analysis can be used to identify unexpected pollution associated with the purity of the distilled water, inappropriate cleaning of the containers or contamination through air absorbed by the samples during the sampling process.

2.3 Solid Waste Sample Collection

One of the most important parameters for solid samples is how representative they are of the place being studied. Many factors affect this representativeness, but the most important is the degree of preliminary information about the sampling site. Many geological maps exist, to different scales, which can serve as a starting point for comprehensive knowledge of the sampling site. The selection of a good sampling model, appropriate instruments and safe storage will result in a good program of sample collection. If the analysis is for environmental reasons, horizontal samplings are recommended since they are more representative of the surface contamination. With sediment samples, the main problem in trace analysis is to obtain a representative sample. Under normal conditions, the best place to draw sediment samples from a lake is the deepest part of the lake, where the turbulence of the water column is at a minimum. However, for the purposes of trace analysis to assess pollution, the sample should be collected from places near to the discharge points or the coastal areas, which are often those that show greater turbulence. Sediments that have been deposited at the bottom of the lake consist of particles of different size, different hydrodynamic properties, and different chemical composition. These particles originate from algae, fecal pellets, and precipitated compounds whose composition has exceeded the solubility product, etc. The first problem for soil sampling is the soil itself, due to the heterogeneous distribution of particle sizes, chemical composition, etc. which makes it impossible to standardize on sampling and pretreatment procedures. A second aspect to consider is the users’ expectations of soil research programs.
**Table 1** Summary of requirements for sample collection and manipulation. (Reproduced from *Standard Methods for the Examination of Water and Wastewater*, 19th edition, 1/22, 1995, by permission of the American Public Health Association.)

For determinations not listed, use glass or plastic containers; preferably refrigerate during storage and analyze as soon as possible.

a P = plastic (polyethylene or equivalent); G = glass; G(A) or P(A) = rinsed with 1 + 1 HNO₃; G(B) = glass, borosilicate; G(S) = glass, rinsed with organic solvents or baked.
b g = grab; c = composite.
c Refrigerate = storage at 4°C in the dark.
d Environmental Protection Agency, Rules and Regulations. 40 CFR Parts 100–149, July 1, 1992. See this citation for possible differences regarding container and preservation requirements. NS = not stated in cited reference; stat = no storage allowed, analyze immediately.

BOD, biochemical oxygen demand; COD, chemical oxygen demand; TFE, tetrafluoroethylene.

2.4 Laboratory Sample Reception and Storage

Before analysis, the water samples are generally stored in one or more bottles or bags, which are made of glass, polypropylene, polyethylene and/or PTFE, each of these materials offering advantages and disadvantages. Once the sample has been taken, all the efforts will be directed towards minimizing the handling. The samples can change physically or chemically; this is why it is necessary to preserve them from deterioration. The preservation is important, since samples that don’t require pretreatment should be kept at 4°C as soon as they have been drawn and filtered. If the period of storage is longer than 2 or 3 days, it is convenient to maintain them at lower temperatures (down to −20°C) in plastic containers as this reduces the activity of the bacteria. Samples for metal analysis should be acidified with nitric acid to a pH lower than 2. Those samples that will be analyzed by dissolved metals should be filtered before acidification. After preservation, they should be kept at 4°C. As a general rule, 1.5 mL⁻¹ of ultrapure HNO₃ per liter is used, as this is sufficient to give an appropriate acidity to the samples. All apparatus that will be in contact with the samples should first be cleaned and washed rigorously with 6 N HCl, and then with an excess of ultrapure water. The membranes used for filtering should be washed in 5 N HCl and then washed thoroughly with twice-distilled water. Great care should be taken to avoid sample contamination; twice-distilled or ultrapure water should be used to dilute and wash the material, and the acids and all other reagents used must be of high purity. All samples should be labelled at the site where they were collected; self-adhesive labels should be used to avoid false identifications. The labels should have at least the following information: number of the sample, name of the person who carried out the collection, date, time and place. A field record book should also be kept, containing all data regarding the sample collection process.

2.5 Sample Reduction and Homogeneity

Only a fraction of the field sample is used, and since this fraction undergoes the whole handling process, it is
necessary to keep in mind the possible contamination that could take place during the procedures and storage. Sediment and soil preparation involve drying and sieving, and in special cases size reduction by milling. The 63 µm fraction is suited for most chemical analyses, but it is not sufficiently abundant in many soils and sediments, where only few grams can be obtained. In these cases the particle size will be defined according to the purposes of the study. Furthermore, it is sometimes necessary to perform detailed examinations of the influence of the sieved and milled particle size in the samples under study. Soils and sediments should be kept in humidity-resistant containers. Drying temperatures should not be higher than 65 °C, since volatile elements present in the sample can be lost at higher temperatures. When drying, it is necessary to avoid the sample becoming a dry mud, since this makes the disintegration more difficult. After drying, the sample can be disintegrated and sieved. The object of the disintegration is not to mill the material but to break down the pieces to obtain a natural grain size distribution. The sample should preferably be sieved through a silk or synthetic fiber sieve, since stainless steel sieves, besides being more expensive, have usually been welded during their production. The sieves should be cleaned, preferably with compressed air.

3 LABORATORY CONDITIONS FOR SAMPLE PREPARATION

This section presents the basic conditions that a laboratory should meet to carry out work related to sample preparation, prior to analysis. Element concentrations in environmental materials can range from percentage levels down to a few parts per billion. Considering the very low concentration levels that will be analyzed and the special elements (e.g. lead, cadmium, arsenic, mercury, selenium, chromium, etc.), a clean area of the laboratory should be chosen for performing this activity.\(^\text{14}\) Interesting work was carried out by Kanatharana et al.,\(^\text{15}\) who established a clean laboratory from a traditional chemistry laboratory. In the last decade, in order to carry out environmental studies in Antarctic snow and ice,\(^\text{16–19}\) the need to determine different heavy metals at the lowest concentration levels (down to parts per billion) has been increased. Boutron\(^\text{20}\) describes a laboratory for the reliable determination of several heavy metals at picogram per gram concentration levels in the snow and ice of Antarctica and Greenland. This laboratory was developed in collaboration with Patterson’s group of the Technological Institute of California.

Particular care should also be taken regarding the quality of the reagents and materials that will be used, since these are important sources of contamination. Likewise, it is necessary to keep in mind the quality of the apparatus and instruments used in the sample decomposition processes. This is also the case with hot plates, fume hoods, heating blocks, etc., since during the sample decomposition process, copious fumes and highly aggressive vapors are usually generated with most of the inorganic acids. This situation could cause damage to the instruments, as well as being a major source of contamination. Special care should be taken when cleaning the materials and containers used in the sample preparation processes, especially with substances that are strongly attached, such as the grease used to lubricate the taper joints.\(^\text{21–23}\) The use of mixtures containing chromic acid should be avoided as much as possible, because of the risk when using this acid.\(^\text{24}\) Attention should be paid to selecting the quality of the cleaning substances, since some pollutants that enter this way could significantly change the final results.

The Standard Method\(^\text{25}\) gives particular consideration to security in the laboratory, since the characteristics of the work mean that personnel are potentially exposed to inhalation of different types of gases, as well as injuries such as burns and, to a smaller degree, poisoning by ingestion. Good training on the risks and precautions that must be taken in laboratory work is a necessary policy. Detailed and practical information appears in the manual by Bernabei.\(^\text{26}\)

3.1 Laboratory Environment

One of the important factors to consider inside the laboratory is control of the air that enters during the analysis of trace and ultratrace elements in environmental materials, since this could be the cause of possible contamination. This problem has been increased by the increase in atmospheric particles due to industrialization. Pollutants that circulate in the atmosphere in the form of powder, fog or smoke can enter the laboratory through the ventilation systems, which is why the composition of the laboratory air becomes similar to that of the surrounding atmosphere. Usually, there are solid and liquid particles in the air derived from natural sources or coming from industrial processes. To achieve a clean atmosphere in the laboratory, in the first place it is recommended that all air inlets, such as the air-conditioning systems, and the heating and ventilation systems, are filtered efficiently. It is advisable not to smoke in the laboratory where the analyses are carried out. Painting, welding or other types of activity that would alter the normal atmospheric conditions should also be avoided. When performing special work, it is convenient to select and maintain an area of the laboratory under essentially clean conditions, in which
the walls and floor should be painted with epoxy-type paint and the amount of people entering should also be reduced. All unnecessary bookcases and pieces of furniture should be eliminated, since these can be sources of dust accumulation. All the windows should be tightly closed and sealed to prevent the entry of dust.

However, it is necessary to keep in mind that unless the work is carried out in a highly polluted atmosphere, the contamination that comes from the air is usually not the most critical in the analysis process. In general, the most sensitive situations are related to contamination from the reagents and containers, especially when they are subject to rigorous digestion processes. For this reason, before making big investments in building special clean rooms for the preparation of samples, it is necessary to carry out a study that determines if the contamination problems really come from a polluted atmosphere. Often good classification, suitable cleaning and appropriate selection of the quality of the reagents and glassware are enough.

3.2 Apparatus and Equipment

The first activity in the preparation of samples for elemental analysis is to measure a quantity of material. In the case of solid samples, this is carried out using an analytical balance. Consequently, it is necessary to take special care with the calibration of this instrument, since errors at this initial stage are difficult to detect and can invalidate the final results. It is usually advisable that this calibration be carried out daily, using several types of analytical certificate weights. The later stages in the preparation of solid samples involve material decomposition processes, which are usually carried out by means of aggressive attacks with inorganic acids.

Usually the apparatus used in the sample decomposition processes, such as hot plates, digestion systems and fume hoods for vapour extraction, is exposed to an atmosphere containing inorganic acid vapours. For this reason, the most important factors to consider at the sample digestion stage are the quality and the efficient operation of the gas extraction systems inside the laboratory. Highly efficient fume hoods which incorporate electronic detection systems are available. They also warn the operator when the extraction speed slows to dangerous levels. When HClO₄ is used in the sample decomposition process it is necessary to use hoods specifically designed to expel the dangerous vapours of this acid from the laboratory. To protect the hood from the action of HClO₄ and other corrosive reagents, the entire base of the interior is built of PVC. Hoods where the interior is built from a single piece of stainless steel 316, integrating the work surface and the waste discharge, are also used, but they are not suitable for digestions involving hydrochloric and nitric acid mixtures.

The hot plates used for the sample digestion should ideally have a cover manufactured from ceramic material, or alternatively from aluminum. Aluminum covers offer a more uniform temperature on the surface, but are less resistant to aggressive atmospheres. Some hot plates are specially designed for remote operation in hoods or other corrosive atmospheres, and the controls can be placed up to 1.0 m from the hot plate, for security and convenience. The best plates are made of steel covered with ceramic, and a cover that is especially resistant to corrosive vapours protects the electric cord that goes from the hot plate to the control. To a smaller degree the oven muffles are also affected by some of the corrosive substances that are produced from the sample decomposition processes. The risk of contamination of the samples is the main worry during the use of these items. In general the corrosiveness of the acids used in the digestion processes oxidize the component materials of the apparatus, a situation that can be a source of contamination. On the other hand, the movement of the air inside the hoods during the digestion process can also be a source of contamination.

For solid samples the preparation stage prior to decomposition habitually involves disintegration, sifting, and occasionally milling. Special care should be taken when selecting the types of material to use in these processes, because of the difficulty in evaluating the contamination introduced by the blank determination, as it is impossible to keep the blanks constant during these operations. It is necessary to carry out periodic and systematic maintenance of the apparatus used in the processes, since it affects the quality of the results obtained. However, the greatest source of error is associated with the sample gathering and chemical preparation processes.

3.3 Reagent Quality

The reagents should be at least of analytical quality according to the specifications of the ACS. For work where the determination of trace and ultratrace elements is required, it is necessary to use high purity reagents. The quality of the reagents used for sample preparation is important, since they could be sources of contamination. If the concentrations of the pollutants are very low, this could have an important effect on the final determination of some elements, due to the quantity of acid that is usually used in the digestion processes.

Different suppliers have produced a great variety of these reagents, with guarantee certificates that indicate that they can be used to analyze different elements at required levels, without contamination problems. Figure 1 shows the certificate of analysis for Suprapur nitric acid and Figure 2 shows the corresponding certificate for hydrochloric acid, both from Merck. Ultrapure...

reagents are expensive, and cost several times as much as their analytic equivalents. Therefore many laboratories have opted to produce the inorganic acids that they need by means of a sub-boiling system. The laboratories usually use this apparatus to obtain HNO₃ and HCl, since they are the most frequently used acids. These acids are also advantageous because of their low boiling points, unlike sulfuric and perchloric acid. Perchloric acids have the added difficulty that they are dangerous.

Water is the solvent most used in the laboratory and is therefore most important. At present, many procedures exist for the purification of water used in the laboratory; including distillation, deionization, membrane filtration and reverse osmosis. Depending on the quality of the feed water and the volume of pure water required, it may
be necessary to combine two of these systems. The ASTM establishes three categories regarding the quality of pure water for use in the laboratory, as shown in Table 2. Type I water is used for the preparation of solutions when trace and ultratrace elements are to be analyzed with maximum accuracy and precision. This water is obtained using a mixed resin, which eliminates dissolved inorganic compounds until a resistivity of 18 MΩ cm is reached. It is also passed through active carbon cartridges to eliminate dissolved organic matter. Type II water is recommended
for most laboratory tests where the analysis of elements is not required to trace levels. It is prepared by distillation, and is recommended for use when it is important that no organic impurities are present. Finally, type III water is satisfactory for qualitative analysis. It can also be used for general glassware cleaning. It is obtained by distillation, deionization in mixed resin or inverse osmosis.

### 3.4 Container and Glassware Quality

Sample collection in the field is usually carried out using polypropylene or polyethylene containers, which should be of high quality and not coloured, since the presence of pigments means that they contain elements that could introduce some pollutant into the sample. Borosilicate glass should be used in the laboratory, and should meet international standards such as DIN/ISO 3585. For special work, quartz glass should be used. Borosilicate glass has the advantage of resisting acids, salt solutions, organic substances and also halogens such as chlorine and bromine. It also has a relatively good resistance to alkaline solutions. Only fluorohydric acid, concentrated phosphoric acid and strongly alkaline solutions attack the surface of the glass at high temperatures. Glass should not be exposed to abrupt changes of temperature, for example it should not be removed from a hot oven and placed on a laboratory surface that is cold or wet. This is especially important in glass apparatus with thick walls, such as filtering flasks or desiccators. Also glass apparatus should not be subjected to abrupt changes of pressure. Glass items such as Erlenmeyer flasks should not be subjected to pressure or vacuum.

### 3.5 Glassware Cleaning

Once field samples are received in the laboratory, and before beginning the analysis, the exterior of the containers should be washed with nitric acid, and then rinsed with high purity water to avoid possible contamination. A series of products have been developed for cleaning glassware or plastic, ceramic or metal containers used in the laboratory. These products have the advantage of being free from chlorine, and of being environmentally friendly, since all the components are biodegradable. Some varieties are also free of phosphate, which means that they can be used to clean material that will later be used to determine this element at trace levels. The products are quite reliable, since they clean plastics, glasses, and metals carefully, with analytic purity, and without leaving residues.

To take the best care of laboratory apparatus, it should be cleaned immediately after use, at low temperatures and for a short time. This is the only way to prevent dirt sticking and to avoid damage to the glass due to adherence of chemical substances. Laboratory glass should never be cleaned with abrasive agents since they can damage the surface. In the immersion bath process, the laboratory glassware is placed in the cleaning liquid for the period of time recommended by the detergent manufacturers. It is then rinsed with flowing water and finally with distilled water. It is not advisable to expose the material to the cleaning solution for a long time, or to increase the temperature, except in the case of persistent dirt. Long periods of contact with the detergent at temperatures of 70°C should be avoided, since some alkaline agents in the detergent can destroy the graduations. Cleaning in a dishwasher is a more careful treatment than cleaning in the immersion bath, since the glassware is in contact with the cleaning liquid only for short washing cycles. Boutron recommends extremely rigorous procedures for cleaning plastic, PTFE and glass materials when the determination of metals is required at picogram per gram levels. The initial cleaning solution should contain up to 25% high purity nitric acid in high purity water.

### 3.6 Clean Analytical Laboratory

The use of clean laboratories with air filtered through HEPA filters is obligatory if reliable measures of heavy metals and other elements to trace and ultratrace concentration levels are required. Classification of clean atmospheres is based on the maximum number of particles between 0.5 and 5.0 mm diameter in the volume of air that exists in a certain space. Table 3 shows the different classes of filtered atmospheres. It has been proven that the most efficient HEPA filters are the dry type, since they have a greater capacity for the capture of small particles. The laminar flow hoods that are used...
in clean places for preliminary sample manipulation are designed to protect the operator, the product and the laboratory environment. These cabinets are not recommended for work in the presence of volatile toxic reagents. Two vertical laminar flow clean benches were used by Boutron\(^2\) for the most critical contamination problems, and for operations that generate vapors, such as the evaporation of acid solutions.

### 3.7 Safety

Laboratory activities related to the handling of chemical products and apparatus can be dangerous to employee’s health. It is important that employees are aware of the risks that are present in a laboratory and the prevention mechanisms. The main safety features that should be available in a laboratory are fire extinguishers, showers, eye washes, storage facilities, gas extraction hoods, and warning signs. Clothes are the most important means of protection, and for this reason should be made from material that is resistant to possible acid or alkali splashes. Gloves should be resistant to hot inorganic acid vapours, and safety glasses should be made of shatter-proof glass. It is also sensible to have breathing apparatus for special situations.

The chemicals usually used in the laboratory are quite safe if they are employed carefully, while respecting the warnings on the product labels. Special care should be taken when perchloric acid is used, since this reacts violently or explosively when it comes into contact with organic matter. Hoods that have been used with perchloric acid should not be used with organic reagents. It is best to have a fume hood exclusively for work with perchloric acid. Risks can be reduced by taking the following precautions.

- Do not add HClO\(_4\) to a hot solution that contains organic matter.
- If samples contain organic matter always test first with HNO\(_3\) before the addition of HClO\(_4\).
- Avoid repeated evaporation to vapours when working in hoods. If necessary, use special hoods for HClO\(_4\).
- Never evaporate to dryness samples that are digested with HClO\(_4\).

### CAUTION don’t use perchloric acid for the digestion of membrane filters.

The analysis of waters involves many risks, so it is advisable that during the sample manipulation processes the analysts use plastic gloves, preferably disposable ones. When working with very polluted samples, as residues or wastewater, pipette-fillers should be used to avoid ingestion accidents, preferably pipette fillers with disposable tips. Untreated waters can contain water-borne microorganisms, so it is necessary, before washing the glassware, to decontaminate all the used pipettes, by placing them in a jar containing a disinfectant solution. To avoid contamination by contact, it is important to maintain appropriate personal hygiene, which means frequently disinfecting the hands and the work surface.

Electrical installations, connections and apparatus should be installed according to the correct standards. Incorrect use of this equipment can lead to serious hazards, such as fires, explosions and electrical discharges. Protection or security devices should be prepared for transmission belts, pulleys, chain transmitters, axes and other types of mechanical transmission apparatus. The vacuum pump, mixers, mills and crushers also require this type of protection.

### 4 SAMPLE PREPARATION FOR WATER ANALYSIS

The procedures used in the preparation of water samples will depend on the purpose of the study, the sample type (natural, waste, sea, etc.) and the analysis technique that will be used. For this reason, it is necessary to decide if the elements to be determined correspond to dissolved metals (those that pass through a 0.45 mm membrane filter are only a fraction of the sample without acidification), suspended metals (those that are retained in the 0.45 mm filter membrane), total metals (elements that are in solution after intense digestion of the whole sample), or metals extracted with acid (elements that are present after the treatment of a sample without filtering with hot dilute mineral acid).

Conservation of the sample is practically impossible, especially if it is a sample of residual domestic or industrial water. In the best case the conservation techniques are only able to slow down the chemical and biological changes that inevitably develop with time after the sample is taken. Some types of samples are more affected

\(^a\) The standard requires laminar flow equipment to attain this level of cleanliness. Since dust particles smaller than 0.5 µm do not introduce substantial errors, 0.5 µm has been adopted as the criterion of measurement.
than others by the conservation, and certain elements will be lost. Some authors outline the advantages of carrying out preconcentration of the sample in the field. Okumura et al. propose a procedure involving iron(II) preconcentration and spectrophotometric analysis of the elution, which is applicable to seawater and fresh waters.

Most of the elements that should be analyzed in an environmental water sample are usually present at very low concentration levels, so it is often necessary to use a preconcentration treatment, before determination of the elements. Zou et al. studied a preconcentration system involving separation of Cr(III) on-line and coprecipitation with lanthanum hydroxide. Luo Fangruo and Hou Xiandeng oxidized thallium(I) with a bromide solution and then preconcentrated it in a column of polyurethane plastic foam. Chikuma and Aoki preconcentrated lead using a chelate-forming resin. Other authors recommend extraction systems to avoid matrix effects. Starostin and Witkiewicz present a review of the literature regarding extraction procedures. Adachi et al. proposed a method in which the vanadium is first separated from the water sample, by extraction with xylene. Paull et al. studied trace elements in seawater, using a high-performance chelating ion chromatographic system, which incorporated a simple chelating-dyestuff-treated column for preconcentration and combined separation of the elements. Because of the interferences that can produce polyatomic ions in the determination of trace elements by inductively coupled plasma mass spectrometry (ICPMS), Bloxham et al. proposed eliminating matrix effects in the analysis of seawater by chelating the analytes on an iminodiacetate-based resin. Chapple and Byrne describe a method in which the seawater matrix interferences are eliminated by a combined process of in situ separation of the analyte and electrothermal vaporization before ICPMS. Special treatments are considered to carry out speciation of some elements. Tanzer and Heumann proposed a methodology for the selective determination of different chemical species of selenium in environmental water samples. Horvat et al. compared the distillation process with other traditional processes in the determination of methyl mercury.

### 4.1 Sample Preservation and Storage

The sampling methods and sample preparation procedures depend on the type of determination and the sample source (surface water, underground water, drinking water, etc.). About 250–1000 mL of water is necessary for a simple determination, although larger volumes would be required in some cases. After collection, the samples should be filtered to separate the dissolved metals, and acidified with concentrated nitric acid (HNO₃) to pH < 2, to prevent adsorption of the analytes on the container walls. For short-term conservation, 1.5 mL⁻¹ concentrated HNO₃ per liter of sample, is usually enough. For samples with high buffer capacity it is necessary to increase the quantity of acid (by up to 5 mL for some alkaline samples), or to use high-purity acid. The acidified sample should preferably be conserved at a temperature of 4 °C to avoid changes in volume caused by evaporation. Under these conditions, samples with metal concentrations of several milligrams per liter remain stable for up to six months. If the levels of metals are of the order of micrograms per liter, the samples should be analyzed as soon as possible after collection. To conserve the sample when the determination of mercury is required, it is advisable to add 2 mL of solution of 20% K₂Cr₂O₇ (prepared in HNO₃ 1 + 1) per liter of sample. If the samples are to be stored for a long period without previous treatment, it is recommended that they are kept at temperatures of −20 °C, in plastic containers. Once defrosted it will be necessary to filter them with 0.45 µm filters and acidify the fraction that will be used for metals analysis.

### 4.2 Sample Preparation

In general when the samples are colourless, transparent, of low turbidity, odorless and single-phase, the total metals are analyzed directly. Samples that contain particles or organic matter generally require pretreatment before analysis of the total metals. Once defrosted it will be necessary to filter them with 0.45 µm filters and acidify the fraction that will be used for metals analysis.

To reduce interference from organic matter and solubilize the associated metal, an appropriate digestion procedure should be used. It is preferable to use a less complex digestion method that allows complete and consistent recovery, but is still compatible with the analytical method and with the metal that is analyzed. Nitric acid decomposes most of the samples in an appropriate form, and nitrate is also an acceptable matrix for most of the chemical analysis techniques.

Some samples will require the addition of perchloric, hydrochloric or sulphuric acid for complete digestion. These acids can interfere in the analysis of some metals and they all provide a more problematic matrix for electrochemical analysis. Prior to the preparation it is necessary to confirm the recovery of the metal for each
digestion and analytical procedure used. As a general rule, HNO₃ is only used in the case of clean samples or materials that are oxidized easily. Digestion with HNO₃—H₂SO₄ or with HNO₃—HCl is easily adapted for oxidizable organic matter; in the case of organic matter or mineral that is difficult to oxidize it is necessary to use HNO₃—HClO₄ or HNO₃—HF. In the case of lead determination in the presence of high quantities of sulfate (for example, determination of Pb in fly ash of a thermal power plant) it is necessary to dissolve the precipitate of PbSO₄. When HClO₄ is used it should be noted that contact of this acid with organic matter can cause violent explosions (see section 3.7). If large quantities of organic matter are present, dry combustion is useful. Balint et al. carried out digestion of wastewater samples prior to the determination of total mercury by spectrofluorimetry. A solution of potassium permanganate was added to a fraction of the filtered sample to cause preoxidation to ionic mercury, and later on the sample was treated with a mixture of nitric and sulphuric acid and kept at room temperature.

**4.3 Concentration Procedure**

When the analysis techniques don’t have the appropriate sensitivity, it is necessary to use concentration procedures. These processes are inconvenient in that the sample is exposed to possible contamination and also, if the water samples don’t come from very pure sources, some elements can be concentrated at levels that could produce interference in the analytical determination. The evaporation should preferably be carried out using some system that minimizes possible interferences. Good results can be obtained if the sample is heated inside a chamber with injection of filtered air, as is shown in Figure 3. To avoid contamination due to atmospheric pollutants during the determination of elements at ultratrace levels, Görlach and Boutron carried out the sample evaporation procedure inside a vertical laminar flow hood, as shown in Figure 4.

The digestion procedures are usually used to concentrate the sample for analysis. Therefore these processes usually require that the sample volume taken for analysis be reduced almost to dryness. Thus in the dissolution stage a much smaller sample volume is used. But these processes have the drawback, on most occasions, of causing

---

Copyright 1990, with permission from Elsevier Science.)
a high concentration of dissolved salts, which are concentrated as a consequence of the digestion process.

4.4 Seawater Preparation

The analysis of seawater is currently one of the most important challenges in environmental analytical chemistry, due to the very low concentration levels required to analyze the toxic elements that may be present. Usually preparation of the sample before analysis is very dependent on the technique to be used. Only the standard procedures during sample collection (i.e. immediate filtration to below 0.45 mm in the field, acidification to pH 1.5 with high purity nitric acid, and conservation at 4°C) are common to all techniques. Voltammetry doesn’t usually involve treatment of the samples, since the saline environment is very advantageous for analysis, but generally the sample is irradiated with ultraviolet light to eliminate organic matter. The direct determination of metals by atomic absorption spectrometry (AAS) with a graphite furnace is practically impossible. The sample is usually preconcentrated before determination of the elements, or matrix modifiers are used. Recently ICPMS has become one of the most frequently used techniques in the determination of seawater. Some authors analyze this type of water without pretreatment, but it is more common to carry out some form of pretreatment, either solvent extraction or column separation.

4.5 Interference

During the preliminary collection or sample preparation treatments, great care must be taken not to introduce metals into the samples. Contact with rubber, metal-based paints, cigarette smoke, and paper napkins, as well as all metallic products, including stainless steel, galvanized metal and brass, should be avoided. Conventional fume hoods can contribute significantly to the contamination of the sample, mainly during digestion with acids in open containers. In the case of tips for micropipettes, care should be taken regarding their origin and quality, since they can be polluted with copper, iron, zinc and cadmium. If this is the case, they should be submerged in 2 N HNO₃ or 2 N HCl for several days, and later rinsed with an excess of deionizing water.

It is essential to check the purity of the acids and the quality of the reagents used for conservation, extraction and digestion. If excessive concentrations of metal are detected, the acids must be purified by distillation or ultrapure acids should be used. Tests with blanks should be carried out at all digestion and filtration stages, and the necessary corrections should be applied to the results.

5 SAMPLE PREPARATION FOR SOLID WASTE ANALYSIS

When selecting a good method of chemical decomposition for elemental analysis, the capacity of the method to completely digest all the elements of interest, without loss of any volatile species, should be borne in mind. Most of the analytical techniques used for quantitative inorganic elemental analysis require that the sample is in aqueous solution, since better homogeneity is achieved in this way. But the process of putting a material into solution is often the most critical part in the analysis, since there are many sources of potential errors, for example partial digestion of the analytes present, or some type of contamination from the containers or chemical products used. Some analyses don’t require the complete digestion of the sample, for example the determination of recoverable elements from sediments. However, on most occasions the total concentration of the element in solution needs to be determined. Therefore systems of open digestion have traditionally been used. The use of aqua regia and mixtures of acids such as HClO₄, HNO₃, HCl and HF are considered the most efficient methods for total elemental digestion. But due to the high risk associated with using HClO₄ in contact with organic matter, some authors have studied the use of H₂O₂ in its place. Decomposition with mixtures of HClO₄, HNO₃ and HCl has proved to be very effective for the total digestion of selenium, and selenium and arsenic, and selenium and tellurium. Other authors have carried out the digestion of arsenic, selenium and antimony using less energetic procedures, digesting the samples with concentrated HCl and HNO₃ and digesting mercury with HNO₃ and then with HCl. Horvat et al. show the advantage of distillation, rather than digestion with hydrochloric acid and alkalis, for the preparation of samples for the determination of methyl mercury. Sample preparation techniques by means of fusion are considered to have little applicability, mainly because the process is slow, and there is a risk of contamination. Smeller did a comparative study of digestion with hydrochloric acid and fusion with lithium metaborate, and considers it more efficient to use the fusion process.

Pressure digestion systems have been used with some success in the preparation of soils and sediments for the elemental determination of trace metals. They have also been used in the preparation of these materials, before total determination of critical elements such as mercury, platinum, lead and cadmium. Takamatsu proposed the use of a high-pressure double bomb for the quantitative recovery of total S from sediments. Zhang and Shan compared the effectiveness of a pressure digestion system and a microwave
system in the decomposition of soils for the determination of rare earths by ICPMS. In the last few years the use of microwave digestion systems has offered the advantages of rapid preparation of samples and reduction of contamination risks.\(^{69,70}\) This technique, which is the same as pressure systems with bombs, has been used in the digestion of marine sediments,\(^{71}\) and also in soils and sediments in agriculture,\(^{72}\) for the elemental determination of trace metals. Good results for the determination of total mercury were obtained by Omba,\(^{73}\) Murphy et al.\(^{74}\) and Kumar and Meeravali\(^{75}\) when applying this digestion technique to environmental materials. Morrow et al.\(^{76}\) used this digestion procedure for the preparation of sediment samples, before the simultaneous determination of Sb, As, Bi, Ge, Se and Te by inductively coupled plasma atomic emission spectrometry (ICP AES). Matusiewicz et al.\(^{77}\) used it for the preparation of marine sediments and later determination of cadmium.

The determination of the total concentration of the elements present in sediments doesn’t give enough information about the mobility of metals. For this reason it becomes necessary to analyze the metals associated with a particular sediment phase. Sequential extraction offers useful information on how the metals are bound to sediments. Many of the outlines of sequential extractions are based on a five-stage protocol, as suggested by Tessier et al.\(^{78}\) Thomas et al.\(^{79}\) used a three-stage sequential extraction procedure on two river sediments, following the protocols proposed by the BCR. Whalley and Grant\(^{80}\) recommend acidifying the extracts after separation, since they detected significant differences in the extracts from calcium carbonate extraction, potassium feldspar, ferrihydrite and humic acid in samples analyzed before and after acidification. However, sequential extraction methods have some detractors. Several authors have criticized the wide use that these procedures have had, because reabsorption effects have been reported during the extraction,\(^{81}\) and because of lack of geochemical specificity.\(^{82}\)

### 5.1 Open Wet Digestion

The acid digestion procedures have advantages over the fusion methods, since the fusion reagents cannot be obtained in such pure forms as the acids, and also an excess of acid in the samples can often be eliminated by evaporation. The total digestion methods are based on oxidation of the matrix by nitric, perchloric and sulphuric acid mixtures. This digestion technique is recommended for many environmental samples, but the danger involved in the use of perchloric acid is one of the biggest disadvantages. Another disadvantage of these digestion methods is the high consumption of chemicals and the possibility of loss or contamination of certain elements. The loss of elements such as B, As, Be and Sb in the form of volatile compounds is a limitation in this type of acid digestion when hydrofluoric acid is used. When selecting an appropriate procedure there is a temptation to dilute the original sample as little as possible, so that the maximum number of trace elements can be determined. Unfortunately this can mean that the concentration of dissolved solids reaches values of 1–2%, which can cause physical problems with the injection of samples in some spectroscopic techniques. Fortunately, several techniques now exist that allow the direct determination of many trace elements in environmental materials, even when the digestion procedure involves a dilution of a hundred times or more.

### 5.2 Dry Ashing

Dry ashing is one of the most common techniques used for destroying organic or biological matter. In this procedure, the sample is put in a crucible (made of quartz, porcelain or platinum), and heated inside an oven muffle until all the organic material is burnt. Finally the small inorganic residue is used in the analysis. Atmospheric oxygen acts as an oxidizing agent. The normal result of the ashing process is an inorganic residue of metallic oxides, sulfates, silicates and so on. However, as the purpose is to determine the concentration of the elements, an appropriate digestion process is necessary to put the elements into solution. It is then possible to consider a soft digestion with inorganic acid or a vigorous attack with mixtures of acids. An alternative to these ashing processes involves passing a low pressure flow of oxygen (approximately 150–700 Pa) through a high frequency electric field to produce excited oxygen. This oxygen flows over the sample inside a quartz tube, oxidizing the sample at temperatures less than 200 °C. The use of low temperatures has the advantage that losses due to volatilization decrease significantly, as do losses due to reactions with the container. One of the problems with this procedure is that the oxygen acts mainly on the surface of the sample. This makes periodic agitation necessary, which causes the process to stop, thus making it quite slow and tedious. Microwave muffle furnaces offer big advantages in the use of this technique, since they reduce the ashing times to a few minutes. They also improve the environmental conditions in the laboratory, since they don’t produce odors and their internal capacities are also quite large. The combination of high heating by the microwaves and the concentration of air (and therefore O\(_2\)) that flows through the porous walls of the muffle makes this equipment an excellent alternative to the ashing processes.
5.3 Wet Ashing Techniques

Wet ashing processes involve heating the sample (containing organic matter) in the presence of an acid mineral oxidizer or mixtures of acids. When the acids are sufficiently strong oxidizers, and the sample is heated vigorously for a while, it is possible to completely oxidize the sample, leaving several of the elements present in the acid solution for analysis.

Wet ashing using concentrated acids (H₂SO₄, HNO₃, or HClO₄), or a mixture of them, is a common and important method for the decomposition of samples containing organic matter. This procedure is particularly useful for the determination of trace metals in a great variety of samples, because many of the elements are transformed into nonvolatile inorganic cations, which remain in the acid solution. Wet ashing can be used for nitrogen, phosphorous and sulfur determination, among the nonmetallic elements, but some elements are totally or partially lost through volatilization; these include mercury, arsenic, selenium, boron, and antimony.

It should be noted that HClO₄ is highly dangerous when in contact with organic matter, since explosions can occur (see section 3.7). For this reason it is recommended that the organic matter is first oxidized with HNO₃ concentrate. Finally, leave the mixture at room temperature and add HClO₄ (preferably mixed with HNO₃) carefully and reheat until complete oxidation. In this form the use of this acid is safer.

5.4 Pressurized Digestion

The advantages of pressure decomposition techniques for the digestion of environmental samples are very important when the quantitative analysis of trace elements is required. Pressure digestion procedures are preferred to traditional methods in most of the laboratories that determine elements in environmental samples. Good reproducibility, very low risk of contamination and no loss of analytes are the main advantages of this system.

One of the most frequently used methods of decomposition over the last few years has been wet chemical decomposition with nitric acid in Teflon® pressure bombs. This digestion has the advantage that many substances which are inert to attack by nitric acid at low temperatures can be attacked successfully at high temperatures while avoiding loss of volatile elements. However, decomposition temperatures that can be reached by this method are limited by the decomposition temperature of the PTFE container. The container volume also limits decomposition in these techniques, since only small quantities of samples can be digested. In some cases the PTFE containers can absorb elements from the solution, and also release elements into the solution, and as a consequence loss or contamination can happen. There is a pressure digestion system that involves the use of quartz containers, thus avoiding damage due to mechanical problems that can take place in PTFE containers when working at high temperatures.

5.5 Microwave Digestion

The microwave digestion system has proven to be a very useful tool, since this technique has the advantage that because the sample can be prepared quickly, the risks of contamination are reduced. The digestion times decrease, because of the energy generated as a consequence of the action of the microwaves on the acid. Contrary to traditional heating, where the heat is introduced from the outside by convection and radiation, heat from microwaves is generated in the core of the solution, and spreads from the inside towards the outside. This system causes rapid heating of the solution, which can reach higher temperatures than the boiling point of the acid. The activity of the microwaves also causes mechanical agitation, facilitating the disintegration of the sample matrix. Digestions at high temperature and pressure provide complete mineralization of the material. Digestion in closed systems ensures complete recovery of the elements being studied. Some difficulties occur in the digestion of materials containing silicates, and for this reason it is desirable that they are treated with HF for better recovery.

Microwave digestion of organic compounds presents problems due to rapid oxidation, which can generate exothermic reactions that are difficult to control. Microwave units now exist in which digestion of the organic matter can be started with a 250 W “unpulsed” program for a few minutes, thus beginning a soft oxidation of the sample and preventing an uncontrollable exothermic reaction. Another microwave digestion procedure consists of an open system in which the heating is generated in the center of the solution, as in a traditional microwave system. This system can be used in digestions with low volatility and high boiling point acids (H₂SO₄, HClO₄, and H₃PO₄).

5.6 Sequential Extraction

Sequential extraction systems are used to determine the different forms of metals in sediments. A sediment fraction of particle size less than 63 µm is subjected to three extraction stages, according to the protocol set down by the BCR. In the first stage a solution of acetic acid is added to the sediment and it is leached with agitation for a period of 16 h. In a second stage, a solution of hydroxylammonium chloride is added to the washed residue, and later the same extraction procedure is reapplied. In the final stage the residue is subjected
to digestion with hydrogen peroxide, and the sample is almost taken to dryness. The residue is extracted with ammonium acetate, using a similar method to the first two stages.

5.7 Sources of Error

In general, during the sample analysis process, the main source of error is the digestion stage, since this is when the sample is usually subjected to rigorous transformations. When the concentrations of the analyte to be determined are more than 100 µg g⁻¹, contamination in routine operations doesn’t greatly influence the analytical results. But these contaminations become more significant when trace element analysis is required, since the use of small quantities of reagents during the decomposition process can have a great effect on the final trace element concentration.

Fusion procedures are generally more efficient than acid digestions, but fusion reagents can increase the concentrations of the dissolved solids to inconveniently high levels. Also, these reagents can introduce important quantities of impurities, increasing the blank levels (and thus the limits of detection) for the trace elements. The loss of some elements due to volatilization can be severe, due to the high temperatures of the calcination processes. However, the problems of loss of volatile elements affect non-metallic elements more than metals. The elements most prone to loss by volatilization are the halogens, S, Se, P, As, Sb, Ge, Tl, and Hg. Other causes of error can be reaction of the crucible during calcination, as well as absorption of some analytes on the crucible walls. These problems can be largely avoided by using platinum crucibles. To reduce negative effects during the calcination procedure, the sample should be mixed with some material that helps oxidation, prevents loss due to volatilization or prevents reactions with the walls of the crucible. The better known materials for this purpose are mixtures containing sulfuric acid, which form nonvolatile sulfates, thus reducing losses due to volatilization. Nitric acid and nitrates of alkaline metals act as oxidizing agents, forming metallic oxides. Hydroxides and carbonates form nonvolatile compounds with nonmetallics, preventing the loss of some elements.

6 ENVIRONMENTAL REGULATION AND METHODS

The monitoring systems require environmental measurements to determine the water quality and the type of waste effluent. The USEPA carries out continuous investigations of new technologies to improve the analytical methods for chemical characterization. Good sensitivity, low cost, reliability, robustness, good precision and accuracy are the main aspects that a new technology should have for the chemical characterization of samples coming from a particular geographic area. For this reason the USEPA has developed and distributed analytical methods to measure the chemical and physical parameters that affect the quality of the environment, including pollutants that can potentially have adverse effects on health. The USEPA has carried out collaborative studies with other laboratories to validate the analytical methods.

The analytical methods published by the USEPA are written as stand-alone documents, so that each method can be removed from the manual, photocopied, inserted in another portfolio, and used without loss of information. The revisions of these methods are usually available in similar formats to facilitate substitution of existing methods as new techniques are developed. This flexibility avoids duplication of material. The volume added to the manual is also small in comparison with the whole. An important aspect of the methods is the consistent use of terminology, which is especially useful in the quality control section. The meanings of the terms are carefully selected, and the definition list is small and consequently easy to understand and to use. The names of the authors of the methods are provided to help users obtain direct support when required. The methods don’t seek to be USEPA regulations, or obligatory for monitoring programs or specific studies. The quality control sections are uniform and they contain the minimum requirements to develop a reliable monitoring program. It is recommended that different practices are used for quality control, such as routine analysis of reagent blanks, analysis of fortified reagent blanks and sample solutions with standard additions, and analysis of quality control samples.

looseness=1 Some authors have used these methods to determine mercury in groundwater and drinking water samples and in drinking water, wastewater, and sediments. In both studies USEPA method 245.1A was used for digestion of the samples. Pyle and Nocerino carried out a combined study with the USEPA to compare AAS, ICPAES, potentiometric stripping analysis (PSA) and X-ray fluorescence (XRF) spectrometry, in the determination of cadmium and lead in soil. The samples were digested using USEPA method 3050. Skip Kingston showed the advantages of using microwave preparation systems using USEPA method 3052, which is considered to be the most flexible and the most used inside the United States. The publication also presents a comparative table of several methods developed by different organizations.

Table 4 summarizes the different methods used in the monitoring programs.

7 QUALITY CONTROL

Information obtained in a chemical analysis laboratory serves as a basis for scientific, technological, administrative and economic decisions, such that the results are recognized and accepted and provide a firm foundation for making the correct decision. At the moment, information regarding the quality of the environment, foods, pharmaceutical and industrial chemicals, etc. is in demand in many countries. Accuracy, which is the degree of agreement between the result and the true value, and representativeness, which is the degree of agreement between the collected sample and the definition of the problem, are the two properties that unequivocally define the quality of the results. The factors that affect the representativeness depend on the sampling, an activity that in general is unrelated to the work of the laboratory. However, accuracy, which should have an appropriate degree of precision, represents the quality of the analytical work. Work that is carried out in the laboratory can be divided into three stages. The first one corresponds to the chemical treatment, and involves the preliminary preparation of the sample, digestion, dilution, separation procedures, etc. The second involves measuring the analytical signs, that is the use of an instrument that generates this information. The last corresponds to the acquisition and treatment of data. The quality of the results, which is the most important aspect, depends on
each one of these stages, and the effect that each phase has on the final result cannot be minimized. Nevertheless, the first stage, because of the variety of operations involved, is traditionally the one that introduces the greatest degree of uncertainty in the final result.\(^{(1,2)}\)

One of the main factors that should be kept in mind during the chemical preparation stage involves the pollutants that can be introduced by the containers (especially in the digestion process), the chemists, the circulation of air inside the fume hoods, etc.

Other factors are related to the behaviour of the sample during this process (loss of elements by evaporation, co-precipitation, digestion of refractory elements, etc.). The first of these factors is controlled by the use of reagent blanks and the second using CRM. As with the reagent blanks, the CRM should undergo the whole process with the sample. A great variety of these certified materials exist, in different matrix types, which can be used to check the behavior of the procedures used. Among the materials most used by different authors are those related to seawaters,\(^{(35,46)}\) river waters,\(^{(90)}\) and soil and sediment.\(^{(11,62)}\)

The main suppliers of these materials are: NIST, BCR, Laboratory of the Government Chemist (LGC), Laboratoire National d’Essais (LNE) and the National Research Council of Canada (NRCC).

Many laboratories have produced this type of material.

### 7.1 Instrument Calibration

The calibration of instruments and apparatus should be a regular activity in all laboratories that work under a quality program. The frequency of calibration will depend on the nature of the instrument, its robustness, amount of use, and environment. It also depends on the demands of the analytical methodology used. The calibration programs should be designed to fit in with the periods of use of the instruments and the periods of time during which they are not in service. Instruments that are used infrequently or those that are particularly sensitive should be standardized every time that they are used. Others will only need periodic calibration, unless there are special circumstances.

Because of the complexity of modern instruments, the design of maintenance programs has placed demands on the laboratories. Laboratory personnel now have difficulty repairing instruments, and normally rely on the technical departments of the makers or their representatives, who offer maintenance contracts that incorporate calibration and validation of the instruments within their quality guarantees.

### 7.2 The Blank

To obtain a good analytical result, it is advisable that a blank undergoes the whole chemical analysis procedure, along with the samples.\(^{(91)}\) This blank should include all the reagents that are used in the preparation of the samples, since many metals are present in the acids and the glassware in significant quantities that can influence the results. If the measurements carried out with the blank give higher concentrations than the detection limit of the method, preparation of the sample should be repeated using purer reagents and/or cleaner glassware. For the analysis of metals it is necessary to check that the glassware and other materials are especially clean. Experience has shown that a blank made with the same acids and subjected to the same digestion procedure as the sample can correct for impurities present in the acids, in the reagent solution or in the glassware.

### 7.3 Use of Reference Materials

Good accuracy is one of the fundamental premises in all chemical analysis, but the problem is knowing with reliability the true value. The use of CRM is one of the mechanisms most used by the laboratories to determine if the results obtained are near to the true values. These materials should satisfy the requirements of homogeneity, accuracy, traceability and stability, as well as such requirements as similarity with the sample matrix and precision. But frequently it is impossible to fulfill all of these requirements. Homogeneity is essential in these materials, to ensure that there are no differences from the certified value either within a single flask or between different flasks. The same situation applies with accuracy and traceability, since these materials are used to verify the analytical results or instrument calibrations. In the case of stability, in spite of being a basic requirement it is not always possible to guarantee stability in all sample types. Also in some cases these materials are sensitive to changes in temperature, intense light, humidity, etc. The value that should be most similar to that of the sample for analysis is the matrix of the reference material, a situation that can be fulfilled quite easily in the case of metals and minerals, but is more complicated in the case of environmental samples, where the analysis of pollutants is required. The certified values of a CRM should include the degree of precision with which it was obtained, which must be as large as possible. CRM are high-cost products, which limits their frequency of use inside a laboratory. For this reason it is advisable to prepare some type of control material inside the laboratory, which must have similar characteristics to the samples to be analyzed. These could be prepared from the samples after some of them had been analyzed several times and the two most similar methods chosen. These materials should be obtained systematically for each batch of samples to be analyzed.
8 DEVELOPMENT OF THE METHOD

The results generated by a chemical analysis laboratory, as mentioned in the previous section, should serve as a basis for scientific, technological or administrative decisions. Thus it is essential in the development of an analysis method that the final results have a high degree of reliability. This requires that a strict control is maintained of all the stages that the sample is subjected to during the analytical process. The development of an analysis method should fit within the laboratory quality system, so that all the information that is generated has the quality level that has previously been agreed upon. It is necessary to make a distinction between the quality of the work that is carried out and the quality of the results that are generated. This last meaning is most often used to define quality in analytical laboratories.

To generate reliable results it is necessary to use a CRM reference that ensures that the result obtained is traceable. Traceability implies a complete sequence of comparisons, so that any stage that has a direct or indirect relationship with a measurement that will be used to generate an analytical result can be subtracted. When development of a method of chemical analysis is planned, it should cover the field or sample type to which it will be applied. If the most important issue is the quality of the result, this can imply a slower analytical response. On the other hand, if the important issue is the speed of the results, this can lead to deterioration in accuracy and precision. It should not be forgotten that the quality of the results has two essential components: accuracy and representativeness. This is because, however good the accuracy and precision of a result, if it is not representative of the original material the result won’t have any value. Only the correct application of a good method can guarantee the quality of the results, which shows the need to maintain the quality control and evaluation systems.

8.1 Writing Up of the Method

To write up an analytical method it is necessary to follow a strict sequence, to avoid causing confusion to other chemists. Jargon should not be used, and if abbreviations are used then they should be defined. The writing should be clear and unambiguous. It is necessary to indicate the critical stages in the analysis and the consequences if they are not followed. The sentences should be short and clearly edited. Different formats have been used to write up methods, but they all, up to a point, cover the same sections. The sections, and their contents, are as follows.

- Method number: a number that uniquely identifies each method will facilitate traceability.
- Title: the title should be brief, and should contain the name of the analyte and the matrix.
- Scope and application: this indicates the matrix type to which the method will be applied, and the technical or instrumental procedures that could be used to determine the elements.
- Summary of method: a very brief summary of the procedure is useful.
- Definitions: acronyms or abbreviations that are used to identify solutions or processes should be defined.
- Interference: elements that could enter the sample solution, as well as materials or apparatus that could potentially cause contamination, are indicated.
- Apparatus and equipment: glassware, plastics, etc. that will be used are listed, plus the precautions that it is necessary to take with some of them are pointed out.
- Cautions and security: the risks involved in the manipulation of certain samples and the use of certain apparatus and reagents are pointed out. The precautions that it is necessary to take are indicated.
- Reagents and materials: the quality of reagents, prepared solutions, water and reference materials that will be used during the analysis process are indicated in some detail.
- Sample preservation and storage: sample conservation systems are indicated, and details of how samples will be stored until analysis are given.
- Calibration and standardization: details of which instruments require calibration, and how the calibration will be carried out, are recorded in this section.
- Quality control: the quality control program that will be applied to the samples is indicated.
- Procedure: the procedure used to obtain a solution suitable for analysis by some instrumental procedure is indicated in detail.
- References: bibliographical accounts of the experimental method, and also details of the validation studies, are indicated.

ACKNOWLEDGMENTS

The author would like to thank Cecilia Navarrete, librarian of the Nuclear Centre Lo Aguirre, for her valuable cooperation in the location of important bibliographic materials. He is also very grateful to Oscar Arlegui, of the Laboratory of Chemical Analysis of the Nuclear Centre Lo Aguirre, for his invaluable contributions to section 4.

This article looks at various factors involved in the first step in biomonitoring, namely the sampling process with special reference to heavy metal levels in living organisms and their interaction with terrestrial ecosystems. Because samples taken in the field naturally form the basis for the entire biomonitoring process, it is vitally important that the margin of error in this step is kept as low as absolutely possible. An important initial step is the decision about which organisms to use and where to gather them. It is important to consider factors such as chemical composition, relationship to the ecosystem involved and the number of individuals available, in addition to the abiotic and biotic factors which influence the amount of heavy metal the organism takes in from its environment, or its bioavailability (heavy metal accumulation is the practical example for biomonitoring used in this article).

How the samples are collected is as important as what is collected, and here various topics are covered, from choosing the most suitable organism(s), to deciding how many samples to take in order for them to be representative of the entire population at that site, to economic considerations. Although exact sampling methods vary according to the organisms involved and there are very few publications in this field, some basic guidelines are given to follow in any case, as well as references to the existing published guides.

1 INTRODUCTION

The damage caused to ecosystems by pollutants can be ascertained by analyzing substrate samples or by determining pollutant concentrations in organisms. An important advantage of using living organisms as opposed to other environmental compartments such as soil, water or air is that an organism exists in a particular ecosystem because of its specific requirements for survival and may therefore be considered representative of this ecosystem. In the context of monitoring programs, the pollutant concentrations found in organisms make it possible to draw conclusions about pollution at a particular location or in whole ecosystems.1

Since airborne and waterborne pollutants are highly subject to dilution by their environment, their occurrence is only temporary and therefore difficult to determine. But if an organism that lives in the ecosystem permanently is used, we may assume that determining its pollutant content will reveal an integrated overall burden at a particular location. Unlike inanimate material, however, living organisms constantly interact with their environment, with the result that their uptake of pollutants is not constant but influenced and sometimes dominated by abiotic and biotic factors. This means that the information on ecosystems yielded by the pollutant concentrations in organisms is at best limited unless the natural, ecological fluctuations are known.2

The interaction between an organism and its environment does not only result in fluctuations in pollutant levels over the course of time, it also affects the geographic distribution of the organisms, which may differ from the substrate-bound distribution of the pollutant at the site.

Before drawing conclusions about the overall burden on the ecosystem from the pollutant concentration found in an organism, it is therefore necessary to determine the variability of the organism’s pollutant uptake in terms of time and space. As a first step in practical analytical work, sampling is of crucial importance since errors that occur at this stage continue throughout the process of data collection and cannot be corrected retrospectively.2–10

Whether the information yielded by an environmental sample is enough to be representative of the pollution of an organism or population, a site or a whole ecosystem depends on how sampling is planned and conducted and
its adjustment to the interactions of the organism or whole populations to be investigated.

2 DEMANDS ON SAMPLING

Since environmental monitoring can never be carried out continuously and thus all observations have to be expressed within a specified framework, any particular process can only be investigated by taking samples. In order to ensure that the monitoring method nevertheless makes the ecosystem as transparent as possible, the sample chosen must contain the greatest amount of information possible which, in turn, has to be applicable to and thus representative of the system as a whole. Like the information content, the degree to which a sample is representative is unknown and cannot be determined directly. But whereas the information content is not ascertained until the process of analysis and evaluation has begun, how representative a sample is, is defined at the beginning, during the planning of the experiment and during sampling.

The following axioms have to be followed to ensure that the samples taken are representative.\(^{(11)}\)

- Axiom 1: The sample taken from the system should have exactly the same chemical composition as the original sample.
- Axiom 2: The probability of being removed from a total population must be the same for each individual.
- Axiom 3: The larger the degree of dispersion among individuals and the larger the number of individuals, the greater the amount of time and effort needed for sampling.

These three axioms for sampling may be regarded as a guideline for dealing with individual problems during the sampling procedure. They can be applied to a large number of questions that arise during monitoring programs.

2.1 Axiom 1: Chemical Composition

The demand made on sampling by Axiom 1 means that a certain number of samples must represent the average pollutant concentration of the overall system. But “overall systems” do not really exist in the ecological sense; they are in fact made up of an arbitrary number of individual systems that may be regarded as an overall system by scientific convention. When determining pollutants in the overall system it is therefore usual to choose individual systems that constitute a large part of the overall system in order to describe this. For example, to describe the pollutant load on a terrestrial ecosystem the sampling and analysis is usually carried out with soil samples. A great advantage of choosing soil to describe a terrestrial ecosystem is that the composition of soil can be depicted in the form of a model, and that the number and weight of the individual samples to be taken can be calculated.\(^{(12)}\)

However, the degree to which a sample is representative of a set of data or an individual system is not an indication of the relevance of its information to the ecosystem as a whole. For example, to describe heavy metal levels in earthworms, further soil parameters such as the pH or cation exchange capacity may be included as well as the total concentrations in the soil samples.\(^{(13)}\)

This means that for certain frames of reference an analysis of the pollutants found in samples of organisms is more suitable for describing conditions in an ecosystem, since we may assume that the system “organism” includes and integrates the individual systems “soil” and “soil chemistry”. The purpose of determining pollutants in organisms within an ecosystem is not to acquire information that has the same value as that yielded by a substrate sample. The intention is rather to acquire information on the integrating effect of the organisms in order to include this in a description of the ecosystem.

The demands on sampling that result from this are discussed below, using heavy metals as an example of environmental pollutants.

3 FACTORS INVOLVED IN HEAVY METAL UPTAKE BY ORGANISMS

3.1 Abiotic Factors

The total of all organisms found in or on a site may be regarded as a biocoenosis of one or several ecosystems. The properties of an ecosystem as a basis for the life of the organisms are governed by abiotic factors such as light, temperature and humidity, and also by the characteristics of the substrate concerned (water, soil, air). Depending on the exposure of the organisms the pollutants may be deposited, and thus collected for analysis, directly on their surfaces. This simplest case of exposure to a pollutant has led to the development of numerous monitoring methods for determining airborne pollution; most of them make use of plants.\(^{(14–26)}\) As sessile organisms they function as a sink for airborne pollutants because of their large surface area. But these pollutants do not remain on the surface; they may be washed off again at irregular intervals by precipitation.

The effect of water on the distribution of polar substances is a fundamental challenge to the determination of pollutants in ecosystems, since water dilutes heavy metal concentrations in general and is largely responsible for their transportation. Even if the quantity of heavy
metals entering an aquatic and a terrestrial ecosystem is the same per unit of surface area, their distribution is greatly dependent on the distribution of the water in the system and the proportion of water contained in the predominant solid matrix (soil, sediment), since the heavy metals are subject to matrix-dependent adsorption and desorption mechanisms. In the simplest case, adsorption to a solid can be expressed by a Langmuir adsorption isotherm (Figure 1). The model assumes that a binding site in the matrix is occupied by a molecule or ion of the pollutant which is thus removed from the aqueous phase of the system (e.g. river water or water in the soil).

If an element has been bound by the substrate it is only available for uptake by an organism if the affinity of the pollutant for the organism is greater than that for the surrounding substrate, or if the affinity of the pollutant for the substrate decreases. In the Langmuir adsorption isotherm this area is marked by the plateau phase of the function in which the adsorption capacity of the substrate decreases and the pollutant remains in the solution.

The adsorption capacity of a matrix for polar pollutants such as heavy metal ions depends on several factors. The most important of the abiotic factors are the structural characteristics of the matrix, the pH of the solution, its redox potential and the presence of other cations. In areas with marine influence the high concentration of sodium and magnesium reduces the uptake of zinc and cadmium. A fall in the pH of the soil does not only permit increased replacement of heavy metals by protons. The buffer systems of the soil are also broken down, and the heavy metals associated with them are released. The same applies to a falling redox potential when there is a lack of oxygen in the soil due to waterlogging. In this case oxidic compounds are reduced and the associated heavy metals released. In the sapropel of a lake or river bed, on the other hand, a positive redox potential can contribute to the oxidation of reduced sulfidic heavy metal compounds and thus to their mobilization. It is important for both forms of mobilization that events such as rain, varying currents or temperature-related water circulation at the ecosystem level influence the oxygen content of the system and thus the mobility of heavy metals. They must therefore be taken into account during sampling as well. Table 1 shows some of the abiotic factors that may influence the mobility of heavy metals in ecosystems.

### 3.2 Biotic Factors

Biotic factors are those factors by which heavy metal uptake by an organism can be actively modified. They are numerous and occur in various forms, which makes it much more difficult to incorporate them in sampling. Their effect is partly due to the fact that the abiotic changes already described can be altered by the organism. Moreover, they include all the ecological and physiological parameters that characterize the interaction of an organism with its environment. Among the latter there are also some that show no connection with the primary uptake of heavy metals at first glance but constitute sources of error during sampling or subsequent analysis.

#### 3.2.1 Determining the Monitor Species

Roth-Holzapfel described the accumulation factors as the quotient of the organism and substrate concentrations of different metals in saprophytic species of a substrate. Depending on the metal and the species concerned (e.g. Diplopora, Lumbricidae, Enchytraeidae, Collembo) the concentrations in the organisms differed in respect

![Figure 1](image-url)  
**Figure 1** Theory of bioavailability of pollutants. The lower the adsorption capacity of the matrix for a particular pollutant, the greater is the bioavailable amount of the pollutant in solution.
to both the essential elements magnesium or potassium and heavy metals such as lead and cobalt.

But differences in the heavy metal concentrations found in the organisms in an ecosystem do not only occur between different taxonomic groups. They are also to be found between representatives of one family or genus and are attributable to the organisms’ requirements for survival. Soil organisms such as earthworms construct extensive tunnel systems and take the soil into their bodies as they do so. This activity results in bioturbation of the soil, intensified contact with the polluted soil surface and an influence of the worms’ digestive system on the mobility of the heavy metals in the soil. Through the uptake and digestion of polluted food, pollutants are released from the food and taken in by the worms. Although different species of worms may exist side by side in the same ecosystem, their pollutant concentration also differs because of their various preferences in respect of food. Anecic earthworms feed on the leaf litter on the surface and the roots of plants. Their tunnels may extend several meters down into the soil. But endogeic earthworms feed on the detritus of the organic upper soil layers, which they rarely leave. Although both types of worms are collected in the same way during sampling and come from the same soil, there may be significant differences in respect of their accumulated pollutant concentrations because of their different ways of life. This means that a strict distinction between species must be made when determining pollutant concentrations in organisms.

3.2.2 Bioaccumulation and Biomagnification

Worm predators, such as hedgehogs, foxes and moles, are subject to the same laws concerning the uptake of pollutants through food, namely that contact with the pollutant through the food chain plays an important role in addition to a pollutant concentration in the surrounding environmental compartment. On the basis of the heavy metal levels found in vertebrates, Made found that insectivores have significantly higher heavy metal concentrations than herbivores in the same ecosystem. For herbivorous species of wild animals, Steinnes et al. demonstrated that the cadmium levels found in the kidneys are higher when the animals have eaten herbs and mushrooms than after the intake of grasses.

The bioaccumulation and biomagnification of pollutants is highly significant for representative sampling, since the accumulation paths can usually be ascertained but remain unknown in the organism to be analyzed; this is because the preceding choice of food depends not only on the organism itself but also on the food available. So if conclusions are to be drawn about the burden on an ecosystem from the concentrations found in organisms, Axiom 1 is violated more and more as bioaccumulation increases. This violation decreases from the euryoecious species without a preference for certain foods to stenoeccious species with food preferences, for in the latter case there is a greater probability of finding a connection between pollutant concentrations and both the food and the availability of food.

3.2.3 Effects of Biomass on the Determination of Pollutant Concentrations

3.2.3.1 Analytical Requirements Concerning the Composition of Biomass

The level of analysis is an important dimension in the determination of pollutants because it sets the chemical and physical limits within which an investigation can be carried out. This means that it also has an influence on sampling and the choice of the organism to be sampled.

Increasing use has been made of inductively coupled plasma atomic emission spectrometry and inductively coupled plasma mass spectrometry to determine heavy metal concentrations in environmental samples. In multielement analysis these techniques have the advantage of permitting a large sample throughput as well as low-detection levels and a very wide linear measuring range.

A specific problem of environmental analysis is that in many cases it is only possible to use a part of the original sample for instrumental analysis. But according to Axiom 1, this part must have the same chemical composition as the original sample. This can be achieved by homogenizing the original sample. If the available measuring technique is sensitive enough it is possible to analyze small quantities of sample material as they are, without previous homogenization. But if the elements to be analyzed only occur in very small amounts in the samples, the detection limit of the equipment makes it impossible to analyze these elements in small quantities of sample material without greatly increasing the risk of analytical error. Homogenization lessens the probability of such error while avoiding the necessity of testing every part of the sample organism separately.

3.2.3.2 Compartmentation

To meet the statistical requirements of sampling it is usual to choose organisms that are both available in large numbers and characteristic of a particular ecosystem. These are often lower plants (lichens, mosses etc.) or lower animals (such as earthworms, snails or wood-lice). Because of the small mass of some organisms, individuals can only be analyzed for elements with relatively high concentrations; otherwise mixed samples have to be made up from several organisms in order to reach the analytical detection limit.

Nd = No data.

One of the problems involved in determining element concentrations from total digestions is that the information yielded by the pollutant levels in the individual organs of the organism is lost. Pollutants are not distributed equally throughout organisms; they may be compartmentalized in different organs (Table 2). If, for example, a storage organ polluted with heavy metals accounts for a small proportion of the overall weight of the organism, a reduction in the size of this organ may also reduce the heavy metal concentration of the organism as a whole, although the effect on the weight of the organism is negligible.

With such compartmentation in mind, it is important to ensure that the distribution of the pollutants in the organism is close to the ideal of uniformity if a representative analysis is to be made from the total digestion of whole organisms. Otherwise ecophysiological fluctuations that cause accumulation or depletion of an element in a compartment may influence the overall concentration of the sample.

3.2.3.3 Influence of Homogeneity on Pollutant Concentrations

The ecophysiological fluctuations in sample organisms include changes in the weight, size and structure of the organisms. In the case of spruce needles, Weissflog et al.\(^\text{44}\) found that pollutant levels varied according to the age and surface area of the needles. The concentrations of polyaromatic hydrocarbons and lead fell significantly as the size of the needles increased. Such information could not have been acquired if needles of different age and size had been homogenized, and the logical conclusion is that only needles of the same size or age must be used if the analysis is to be carried out with mixed samples instead of individual needles. Otherwise the biomass with lower pollutant concentrations may have a diluting effect on the total sample.

The age and size distribution in organism samples is very important, in contrast to the substrates of an ecosystem, for there are relative differences between the two in respect of length of exposure to the pollutant. Whereas a substrate is constantly present at a particular site, the maximum presence of an organism at the same site is the length of its life. This means that the length of exposure of the organism or its compartments to the pollutant is many times shorter. Moreover, the size of an organism is not independent on age as is the case with a substrate; within this relationship it is determined by rapid growth processes.

Using the moss species Polytrichum formosum and Brachythecium rutabulum, Lötschert et al.\(^\text{45}\) and Engelke\(^\text{41}\) showed that the cadmium, lead and zinc concentrations in the plants increased with the age of the tissues. Koeckritz\(^\text{46}\) investigated the copper concentrations in the earthworm species Aporrectodea caliginosa at three sites during one summer and although there was found to be a positive correlation between the levels in the soil and those in the worms, the concentrations in the worms varied greatly over the five-month observation period. At one site a maximum concentration in the earthworms resulted from the fact that the worms fell into a state of drought rigor after a long hot period of intensive sunshine without rain. The event was accompanied by considerable weight loss in the worms. A comparison of the concentrations in the animals as a function of their weight showed that the copper levels decreased exponentially as the weight of the worms increased (Figure 2).

As in the example of the spruce needles, the size distribution of a mixed sample of earthworms is an
important condition for determining average pollutant concentrations over a period of time. The fall in pollutant levels as the size of the needles increases can be explained by the slow growth rate of spruce needles. Although the pollutant-adsorbing surface area becomes larger as the needles grow, it only increases to the second power in relation to the volume and weight of the needles; this results in a dilution of the pollutants by the needles’ own biomass. In *A. caliginosa* this causality cannot readily be achieved. Heavy metal content was found to depend on the weight of the worms in the case of copper but not with lead, cadmium or zinc. Other biotic factors that had the same effect on the result must therefore have played a role.

So the requirement that only organisms of the same species should be used in one set of samples is not enough. It is also necessary to specify that only organisms of the same species, size, age and sex must be sampled or used in the analysis. The list can be extended indefinitely, as long as the requirements contribute to the homogeneity of the sample. Only empirical work can show how far each factor influences the pollutant content of an organism.

### 3.2.3.4 Surface of the Organisms

The accumulation of heavy metals in a monitor organism depends not only on their presence but on the degree to which the pollutants are bioavailable as well. In order to be bioavailable, however, the pollutant naturally first has to reach the monitor organism and come into contact with its surface. In the earthworm example we have already discussed how such contact is intensified by the uptake of soil material into the digestive system, since this active intake increases the surface area. In the case of plants the surface area is enlarged by the assimilatory and respiratory system of the roots and leaves.

Plants come into contact with airborne pollutants mainly through the leaves; such contact can be described as dry and wet deposition. The amount of pollutant coming into contact with a surface depends on its concentration and also on the extent to which it is bound to airborne particles, on the size, nucleation, coagulation, condensation and sedimentation properties of these particles and the affinity of the leaf surface for them. Metals and semimetals are usually emitted in a solid form, bound to dust, whereas organic pollutants are mainly emitted as gases. Fly ash and other dusts with a particle diameter of more than 10µm settle in the vicinity of the emitter, whereas gaseous substances and particles with a diameter of less than 10µm remain suspended for long periods. They are carried by the wind and deposited on the substrates of the ecosystems according to the direction of the prevailing winds and the topography of the region.

Whether or not an element passes into an organism depends on a large extent on its solubility in water, and this in turn depends on its chemical form, the surface of the particles and ambient conditions. According to Rohbock the amounts of water-soluble heavy metals in rainwater can differ considerably, and the effect of the water has an important influence on uptake in addition to the element concentrations deposited on the surface of an organism.

But precipitation does not only deposit elements on the relevant surfaces. Ions already stored and particles adhering to the surfaces may be washed off again, depending on the nature of the precipitation. This means that the type of precipitation has an effect on the uptake processes and that a brief, heavy rainfall results in less pollutant uptake than gentle rain over a longer period. Rühling and Tyler demonstrated a connection between the amount of precipitation and lead concentration in *Hypnum cupressiforme*. In tests on poplar leaves, Wagner showed that the levels of cadmium and zinc in older leaves were similar to those in younger leaves, whereas the lead concentration of the older leaves was twice that of the younger leaves. This phenomenon was explained by the fact that cadmium and zinc were more easily washed off and out of the leaves by heavy rain after the first third of the vegetation period.

This is a further example of how the age of an organism may affect the result of monitoring. In the above examples the age of the organism had an indirect effect on pollutant concentrations because the biomass varied over the course of time. But as the age of the organism increases, so does the likelihood of its being influenced by abiotic or biotic events capable of significantly altering heavy metal concentrations.

The surface of organisms is rarely constant, and in extreme cases, such as the ecdysis of insects, crustaceans and reptiles, it may be renewed completely in the course of time. The surface of plants varies too. According
to Hanway and Weber\textsuperscript{[52]} and Ashley\textsuperscript{[53]} the biomass distribution of the annual soybean changes greatly during a vegetation period. After the plant has flowered the biomass of all the parts increases exponentially, but the leaves and leaf-stalks, that is, the parts with the largest surface area and the greatest adsorption of pollutants, are cast off successively and renewed.

But the surface of plants does not only vary with time as the plant grows; it is also influenced by abiotic factors at the site. Packham and Willis\textsuperscript{[54]} showed with \textit{Oxalis acetosella} that the ratio of the biomass of the leaves to that of the roots increased as insolation decreased. In other words, the plant adjusted to a lack of light by increasing its surface area. An increase in the biomass of the roots in response to a lack of water in the soil may be regarded as a similar form of adjustment.\textsuperscript{[55]}

The thallophytic mosses have a surface that is much more dependent on water than the cormophytes described above, and in spite of their rather simple structure the surfaces of mosses of different species are not directly comparable even if the same amount of water is available. In moss species the capacity to take up cations varies with the morphology of the biomonitor, which may differ greatly according to conditions at the site.\textsuperscript{[56]} To give two examples, \textit{Pleurozium schreberi} has small leaves arranged close to the stems that store the water from precipitation, whereas the leaves of \textit{Polytrichum formosum} stand out from the stems. Moisture from dew and mist settles on these leaves and is then taken in by the plant.

A high surface-to-volume ratio such as that found in mosses not only leads to an increase in the parameters that encourage the accumulation of pollutants; those parameters that promote the variability of pollutant concentrations also acquire an influence.

If the surface area of an organism is very large in relation to its volume or weight, particulate heavy metals adhering to the surface may account for a large proportion of the overall content. It may therefore be advisable to wash off these heavy metals before analyzing the sample.\textsuperscript{[57,58]}

### 3.2.3.5 Seasonal Changes

Organisms growing in unpolluted areas contain a specific basic concentration of all the elements that occur naturally. These originate from natural element cycling – mainly through the atmospheric transportation of soil particles – from the marine environment and from volcanic activity. As a general rule it must be taken into account that the influence of all the biotic and abiotic factors mentioned increases as deposition decreases.\textsuperscript{[18,19,59,60]} The influence of such factors on element concentrations is shown by the fact that the levels in the organisms do not correlate properly with those in the substrates, or that the concentrations in the organisms are subject to fluctuations, sometimes repeated at regular intervals, instead of being stable.

The determination of pollutants in organisms is often used in assessing pollutant loads on ecosystems. Fluctuations in content according to the pollutant and organism concerned must therefore be taken into account in an evaluation since natural fluctuations in the organism levels may overlay inputs from artificial sources, especially when concentrations in the environment are low. Important features of biological fluctuations are the stability of an ecosystem in terms of space, and above all in terms of time, that is expressed in regular events such as the seasons, the tides or the phases of the moon, and the adjustment of the organisms to these rhythms.

The effects of natural fluctuations on a monitoring result can be illustrated by the example of element concentrations in the moss \textit{P. formosum}. In Figure 3 the magnesium, zinc and cadmium levels in the moss at one site are plotted over a period of two and a half years. In order to show the harmony of the fluctuations among themselves the amplitudes have not been adjusted to the scale, that is, only the mean element concentrations correspond to the axis of ordinates. It is plain that the fluctuations in element levels depend not only on the season but also on the mean element concentrations in the moss too, for when the mean cadmium concentrations fall, the amplitude of the element fluctuations is also reduced.

The fall in heavy metal levels in the mosses in spring can be explained by the diluting effect of the plants’ biomass production at this time of the year.\textsuperscript{[22,61]} But without an adequate knowledge of the time resolution of the element concentrations in the moss, any individual measurement would result in misinterpretations of the pollutant load.

![Figure 3](image-url)

**Figure 3** Seasonal fluctuations in metal concentrations in \textit{Polytrichum formosum}. Unlike the mean pollutant loads, the amplitudes have not been adjusted to scale.
on the ecosystem, for the monitor may show a high level of pollution even if the level in the ecosystem is low.

The effect of fluctuation on a monitoring result does not only depend on the element concentration in the environmental compartment and the organism; it also depends on the organism's ability to accumulate a particular element. If an increase in the element concentration in an organism is to be attributed to artificial input, the increase in content must differ significantly from that caused by natural fluctuations. Magnesium and zinc are essential elements for organisms, but the levels found in the example of the moss _P. formosum_ differ 100-fold. We may assume that for these elements special uptake and storage mechanisms exist that are responsible for the high overall level in the organism but are also subject to fluctuations. Because of the natural element concentrations it is not possible to show small inputs from anthropogenic sources within these fluctuations. Nonessential elements such as cadmium are also subject to periodic fluctuations, but because of the low levels in the organism additional inputs are more easily shown provided that they differ from the mean concentrations.

It is essential to find the reason for rhythmic fluctuations in element concentrations in order to compare different monitoring methods in which the same monitor organism has been used. The element concentrations shown for _P. formosum_ follow a rhythm determined by the seasons. Although the months of the relevant years have been entered on the _x_-axis, this is only a nominal scale for the site concerned. In order to compare different sites at different times the time entries have to be made on an ordinal scale with a timing ecological component. On the basis of phenological observations in 50 gardens of identical genetic composition the progress of spring was recorded over a period of 30 years. Whereas the speed of its progress from Portugal to Norway is about 60 km per day close to the Atlantic, its continental speed is only 35 km per day on the line from Greece to Finland. A speed reduction of three to four days per 100 km is also to be expected for every 100 m of altitude.

Since we may assume that the mean period of insolation and mean temperatures and precipitation determine the growth time of the moss, the fluctuations in pollutant levels may depend on these factors too. This means that the time of sampling in relation to climatic conditions may have a lasting influence on a monitoring result although the pollutant burdens on the ecosystem are the same (Figure 4). Scales such as mean temperatures, mean insolation and phenological observations must therefore be checked for their suitability as ordinal scales.

In the above example of the moss _P. formosum_, heavy metal concentrations were studied over a period of one year. The maximum concentrations were observed between December and March. These were followed by a fall in the metal levels from April to May, and until October the values were stable and low. In November the metal levels rose again by up to 100%. Because the metal concentrations fell by about 100% within 100 days in the spring, and in view of the phenological speed with which the spring advances in central Europe, we may assume that the error will be about 2% if the samples are taken at the same time but 100 km apart in a north–south direction. This error may be considered negligible for regional comparisons, but it acquires importance as soon as biomonitoring methods are used at the international level. We also have to remember that the rule about the continuation of errors applies here too, so that even in regional comparisons the overall error increases if the sampling is carried out over a period of several days or perhaps weeks. To avoid this error and ensure that the metal concentrations in moss from sites far apart are comparable, it is therefore advisable to choose the summer months of July and August. These two months are within the period of minimum metal concentrations and allow about 30 days’ margin for variation before and after.

### 3.2.3.6 Loss of Information through Sampling

The above examples have shown that the heavy metal concentrations in organisms may depend on numerous factors. Thus it is only possible to determine the pollutant load on an ecosystem from the levels found in organisms if the parameters influencing the accumulation factor are known. But since these biotic and abiotic parameters affect all the organisms in an ecosystem and the accumulation factors of the organisms differ nevertheless, the sum of all the parameters cannot be universally correct for all the organisms in an ecosystem. Thus, one objective of biomonitoring must be to ascertain the main accumulation parameters for each species and

![Figure 4 Theoretical influence of periodic element fluctuations on the monitoring result.](image-url)
to quantify them. To do this it is necessary to view the monitor organism as a whole and take all the known interactions into account during sampling.

Figure 5 shows the main interactions that have been shown to affect the element concentrations in moss. When attempting to view an organism as a whole within an ecosystem we also have to take into account those factors that do not have a direct effect on the organism. These may include the density of the leaf canopy over a moss population that affects the amount of sunlight or rain reaching the plants.

The abiotic factors that may influence the mobility of heavy metals have already been listed in Table 1. Table 3 shows the biotic factors of heavy metal uptake that have to be taken into account in biomonitoring procedures.

The list shows that the biotic factors are parameters that cannot be ascertained directly during sampling. In order to determine them it is necessary to carry out laboratory or long-term tests in individual cases, or investigations that may exceed the available laboratory capacity.

As far as possible, it is important that the sampling procedure keeps open the option of carrying out such tests at a later date. In other words, it must not affect either the composition of the organisms themselves or their composition relative to each other within the ecosystem. It is important to use sampling equipment that minimizes the risk of contamination from outside sources. The samples must be taken in such a way that the result of the analysis is capable of representing the undisturbed condition of the original sample. The organism must be removed from the population carefully and stored in an equally careful manner. A mistake commonly made at this stage is mixing the samples from one site during the sampling procedure. When plant samples are cut, for example, cell, phloem and xylem sap may exude and dissolve and distribute pollutants. This effect is aggravated by mechanical action on the surfaces through the use of containers that are too small, and the material can then only be used as a mixed sample even if it was intended to analyze individual parts of the organism.

Further practical instructions for sampling are given by Ernst, MacNaeidhe, Markert, and Wolterbeek.

### 4 CONDUCT OF SAMPLING

#### 4.1 Choice of Organisms

Since monitoring procedures can show both the situation with respect to pollution and the accumulation variables, the organisms must be chosen to suit the frame of reference before sampling is carried out. We have already discussed what requirements an organism must meet in order to be representative of the burden on an ecosystem.
But the burden on an organism can also be used to investigate the influence of the accumulation variables on pollutant accumulation. This may be necessary if, for example, the effect of an anthropogenic measure on the behavior of pollutants in the ecosystem is to be investigated in an environmental impact study, even if the measure itself does not constitute an additional burden. An example of this would be the renaturation of an ecosystem after some form of intensive use, in which a former drainage system is abandoned to promote the development of a wetland. As the soil becomes wetter its redox potential may be reduced, and organic acids may be released as a result of anaerobic respiration by the soil organisms. This can mobilize heavy metals and thus make them bioavailable.

The bioconcentration factor mentioned above can be used as a parameter for measuring the availability of a pollutant for organisms. As the quotient of the pollutant contained in the organism and the substrate it describes an organism’s ability to take the substance in.

The bioconcentration factor may increase although the pollutant concentrations in the substrate are constant if an organism takes in a larger amount of a pollutant. The cause of an increased intake may be assumed, initially, to be the sum of all the abiotic and biotic accumulation variables. The object of the investigation is to weight the factors. As in conventional monitoring methods it is necessary to analyze the pollutant concentrations in the substrate and the food in order to determine the bioaccumulation factor or biomagnification factor that describes accumulation through the food. But by determining the accumulation variables (pH, temperature etc.) at the same time, it is also possible to describe the main components of pollutant accumulation, whereas these remain unknown or a matter for speculation with ordinary monitoring methods. When introducing a new monitor organism it is therefore advisable to determine the bioconcentration factor, as this makes it possible to quantify the limits of a monitoring method.

According to Baker, organisms can be classified according to the manner in which they take up pollutants (Figure 6). The nature of the pollutant intake determines whether the concentrations in an organism are capable of representing the burden on an environmental compartment.

The most suitable organism for all frames of reference is a monitor whose pollutant content depends directly on the level in the environmental compartment. The bioavailability of a pollutant for the monitor organism is influenced mainly by abiotic factors and is overlaid only slightly, if at all, by ecophysiological processes in the organism. In spite of linear pollutant accumulation the bioconcentration factor may be less than, equal to or greater than one; any differences are only in respect of the evaluation of the pollutant concentrations and the working range. If the bioconcentration factor is greater than one, even quite small fluctuations in the compartment levels are reflected in the organism levels, as the concentrations are duplicated. If the level in the organism is lower than that of the environmental compartment, only major changes in the pollutant concentration can be detected with the organism. But if the bioconcentration factor of such an organism becomes greater than one we may assume that the bioavailability of the pollutant concerned for the organism has increased as a result of abiotic factors.

In an organism that is ideal for biomonitoring there should be a linear relationship between the concentration of an investigated substance in the environment and the concentration in the organism across a very steep pollutant gradient. But with low environmental concentrations, especially, pollutant uptake is not linear and resembles that of an accumulator or an excluder. The accumulator builds up pollutants exponentially at low environmental concentrations, whereas the excluder only takes in small quantities of the pollutant initially as it is able to regulate uptake physiologically. Not until a tolerance threshold is exceeded does the concentration in the organism increase noticeably.

Table 4 contains a summary of the biotic variables that may influence a pollutant concentration in an organism and their suitability for the purposes of monitoring.

4.2 Axiom 2: Distribution of Organisms

In order to draw conclusions about the concentration of a pollutant in an ecosystem from that in an organism it is necessary to observe statistical conventions which always state that the number of organisms to be taken as samples must be representative of the chosen site. This requirement is not easy to fulfill, for the total population to be investigated and sampled is always unknown and

is also variable. The distribution of individuals within a population, of populations within an ecosystem and of ecosystems themselves is not random. It is determined by climatic, chemophysical and ecological factors. Interactions of the organisms with other forms of life and their own species may lead to changes in population density and distribution over the course of time.

In the following we shall assume that sampling serves the purpose of comparing pollutant concentrations at sites that are different and independent of each other, that is, the sampling procedure is not intended to ascertain the actual distribution at the site.

Since the real distribution of the organisms at each sampling site is unknown, it is necessary to use a sampling technique that is independent of the existing distribution. A method that has been used successfully for sampling the moss *P. formosum* is shown in Figure 7 after Markert.\(^{(11)}\) Independently of the true distribution of the organisms, a random distribution of the sampling points over the site is generated by dividing the area up according to a grid consisting of four zones.

No organisms are taken from the inner zone of about 40 m\(^2\). This is the area in which the physicochemical parameters that may be assumed to apply to the whole location are determined. These parameters include wind speed, temperature, precipitation and insolation, but not the pollution of the soil or its pH.

The second zone serves to separate the first from the third, in which the actual sampling is done. It should not be less than 10–20 m wide to ensure that the sampling has no direct effect on measuring work in the inner zone.

The actual sampling is carried out in the third zone, which is divided up in the form of a grid consisting of at least a hundred squares. The selection of the squares to be sampled is random and independent of the topography and so on. The squares are approached in a clockwise
Figure 7 Conduct of random sampling that is independent of real distribution. (a) Uniform: uniform distribution results when organisms avoid each other and thus create territories. In the case of plants, uniform distribution may occur if the same resources are used for growth or if the plants inhibit each others growth. (b) Contagious: aggregations may form if, for example, a food resource is used by several organisms or the presence of one individual leads to that of others as in the case of flock formation. (c) Random: random distribution results if the probability of occupying a point within an area is the same for each organism and the presence of one organism does not prevent that of another.

direction to ensure undisturbed sampling. Should a square contain no organisms they may be sought in a clockwise direction around the point. During this simple random sampling procedure each square is only sampled once. It is therefore termed sampling without replacement, which is more precise than sampling with replacement.\(^{65}\)

Since the analytically determined mean of the pollutant concentrations in the organism population at one site is intended to enable a comparison between different sites, the number of squares sampled has an important influence on the power of the method to differentiate. According to Eberhardt,\(^{66}\) the number of samples required to carry out statistical procedures increases exponentially as the ratios of the means to be compared decrease. This means that it is not possible to state an exact number of squares to be sampled in this context, since the number depends on the frame of reference, the desired resolution of the method and the funds available.

4.3 Axiom 3: Economic Aspects of Information Content

In biomonitoring projects to determine the pollution of ecosystems, the target for the ratio of the means is often set too low for the number of samples taken. Because of the factors described above that influence the uptake of pollutants by organisms there is a great deal of variability in pollutant concentrations within a population sampled at a particular time. Standard deviations of 50–100% are the rule rather than the exception. A further difficulty is that a natural fluctuation in the pollutant concentrations may find its way into the result as well. Although both of these phenomena can be quantified and included in the result, the effort and expenditure required raises a question about the value of the information yielded by monitoring.

Since the pollutant concentrations and environmental conditions in an ecosystem are constantly changing, the results of monitoring only have the temporary character of a time window\(^{21}\) and thus a limited information content. From the economic point of view the effort required to acquire the information must not exceed the value of the information. So if the ratio of the means to be compared is set very low (to achieve a high level of differentiation), the researcher is obliged to collect a large number of samples within a very short time. The time factor cannot be manipulated by the researcher, since it is determined by the natural fluctuations and the mobility of the pollutant in the system. The only variables that can be influenced are the number of sites to be sampled and the number of samples per site. Thus an important factor in practical, representative and comparative sampling to determine environmental pollutants in biological matrices is the personnel required to carry out the work.

Figure 8 shows the information content of sampling as a function of the work carried out. This general description

![Cost-Benefit](image-url)
of the relationship between work/cost and the resulting benefit is applicable to all the steps in biomonitoring and must be taken into account at the planning stage.

Although the method of random sampling described above is independent of the actual distribution at the site, an analysis of the individuals from one site reveals that their pollutant concentrations rarely show a normal distribution. In addition to binominal and Poisson distribution, the most common forms found in environmental samples include negative binominal distribution, which requires a larger number of samples. But if the necessary number of samples was not collected at the given time this does not mean that the sample is useless; it does, however, mean that the comparability of different locations has to be adjusted to the distributions found. As we have already said, the real distribution within the population is unknown at the time of sampling and cannot be determined until the results are evaluated. By this stage the time window for sampling has in all probability closed, so that additional sampling to adjust the number of random samples to the existing distribution is not permissible.

4.4 Influence of Size of the Organisms on Number of Samples

To show the distribution of a pollutant within a population it is necessary to carry out the pollutant analysis at the level of the individual, and this gives rise to the requirements described above in respect to the minimum size of the organism and the homogeneity of the biomass to be analyzed. In order to determine the manner in which pollutants are distributed statistically in a population the preparation of mixed samples must be avoided, and the biomass of an organism must therefore be sufficient to reach the analytical detection limit. If this is not the case, and the preparation of mixed samples is unavoidable, the number of random samples increases by the factor that is required in order to obtain a representative result for individuals of one size, age or other phenotypical characteristics.

5 HOW TO CARRY OUT A BIOMONITORING PROCEDURE

The aim of biomonitoring is to draw conclusions about the impact of heavy metal accumulation in organisms. The precondition is that all variables described above that might influence the heavy metal content in organisms are either minimized or known. As the methodical and measuring work involved entails significant cost (both financial and time-related), methodical conventions must be stipulated, aiming to guarantee a high level of “ecological homogeneity” of the examined material. This is even more true if the monitored organisms or their accumulation behavior is unknown.

In order to deduce the impact of heavy metals on ecosystems and exposition paths from the heavy metal content in organisms, it is imperative to ask if the corresponding organism represents the exposition path appropriately, thereby keeping in mind that many organisms of one and the same ecosystem can be exposed to various paths of heavy metal accumulation. Even though moss, for example, can appear with many plant communities in one ecosystem, its way of accumulating heavy metal differs, due to its thallophytic ecology and physiology, from the one shown by cormophytes in the same system. As a consequence, the simple measuring of heavy metal content in moss can only provide evidence about heavy metal exposition into the ecosystem via the air, whereas the impact of heavy metals on the soil can only be evaluated by means of other representative species.

In order to compare different monitoring procedures, it is necessary to select representative microorganisms and to take representative samples. So far, only very few practical guides (e.g. Markert, Wappelhorst, Rühling, Tataruch and Herpin, Markert, Siewers and Lieth) have been published. This is because of the variety of exposition paths, types of ecosystem, biotic and abiotic mechanisms of accumulation, and the diverse demands of any biomonitoring process. Does it aim to determine ecophysiological accumulation variables or background impact, or to determine a source of emission systematically? As no generalization is possible, we will sum up only those factors that are relevant for a monitoring, which must, however, be adjusted to the corresponding kinds of investigation and organisms (Figure 9). In selecting an organism to be monitored, sampling sites, the samples themselves, and methods of analysis and assessment of data, the researcher does not face the challenge of collecting as much data as possible on the basis of a corresponding quantity of sample material. The crucial task is rather to minimize the heterogeneity arising from the many ways ecological factors can be combined, that is, to minimize it methodically in such a way that the findings can allow a distinct statement about the actual aim of the investigation to be made, which here is to determine the heavy metal content.

5.1 On-site Sampling

In order to assess representative data, it is imperative that the material contained in the sampled organisms is not damaged during the sampling process itself. As instrumental analysis cannot be applied on the site, the samples must be very carefully collected, transported, stored and processed. To avoid contamination plastic gloves must be worn, and the samples must be taken with
metal-free tools (e.g. ceramic scissors, plastic tweezers) and be stored and transported in plastic containers. It is important to ensure secure transport and storage until measurement can be carried out.

It is also imperative for the researcher not to adulterate the sampling site itself. Especially when monitoring is carried out at one site over a long period of time, and when samples are taken consecutively, researchers must take care that the site disposes of a sufficient quantity of monitored organisms in order to avoid an abundant decrease which might provide locational advantage to other individuals of the same type or of another kind of organism. This could lead to increased growth of the remaining monitored organisms, and thus influence their capacity to adsorb heavy metals.

Assuming that the site is ecologically stable, it is likewise imperative to avoid deterioration of the microclimate which can be triggered by sampling. This includes, for instance, breaking twigs and branches, but also treading on the sampling area. Fixed paths should be used, in particular when samples are to be taken at consecutive dates, because, especially with plants, such damage will not necessarily be evident during the following season. However, a lasting change in the heavy metal content of such organisms can occur.

In order not to adulterate the sampled organism itself, the damage inflicted upon any one organism during sampling must be reduced to a minimum. This means that parts of the plant should not be removed by tearing or breaking, but by using scissors. Organisms are damaged once they are put under stress during sampling. An example is the collecting of earthworms using formaldehyde, electricity or mustard extracts, which aim to drive the earthworms out of the soil and to the surface. Earthworms react to these stress factors by producing coelom liquid; in turn, coelomocytes, which are rich in heavy metals, emanate from the body of the earthworms, leading to an adulteration of data. Sampling

Figure 9 Ecological targeting.
should therefore be carried out by hand, even though this might take longer.\(^{(56)}\)

The above described autolysis of organisms can cause the same errors in the assessment of sampling as does the human-caused damage to organisms. In both cases, liquids occurring naturally in the body can be emitted and distributed throughout the entire sample. This unwelcome homogenization of samples on-site must be minimized by not squeezing the samples in the sampling container, and by freeing them from foreign substances such as soil or leaves before placing them in the corresponding containers. This is important because body liquids can cause the heavy metals contained in the sample to mix with those of the foreign substances. It is likewise imperative to put the sampled organisms into cold storage on-site, but not to freeze them. Cold storage slows down the autolysis of the sampled material, avoiding stress factors by slowing the metabolism of invertebrates, which cannot always be killed on-site as they must empty their bowels for several hours before being processed for analysis.

5.2 Conclusions

The representative sampling of organisms of one ecosystem does not only demand high scientific competence of the staff dealing with the processing and the analysis of the samples, but also of the sampling staff, because none of the mistakes made during the sampling activities can be undone afterwards. Apart from the duty of care demanded of scientific staff, other factors are important. Thus the sampling activity must not only consider the statistical aspects of a representative group of organisms, but also account for ecological and economic factors. Only a thorough study of one organism can provide the guarantee that the investigated organism reflects the desired exposition path at the time of sampling. However, even a complete investigation does not entirely allow for a consideration of all ecological parameters concerning one particular organism. This means that even during the planning of the sampling, its execution must be defined in such a way that its information value does not suffer and that the broader view does not disappear behind the variety of ecological possibilities considered. This is only possible by balancing the heterogeneity of samples taken from one area with homogenizing sampling from similar sites, which show similar microclimatic conditions, and so on.

Although it is seldom mentioned in this context, the economic aspects of sampling should not be neglected. In contrast to sample processing and heavy metal analysis, sampling is, within the biomonitoring activity, the least cost-intensive element. However, as sampling is the first link in a long chain of analytical work, and because errors committed at that point will only become evident after evaluation of the results, ensuring quality at this stage should outweigh other cost considerations.

The slurry is injected into the furnace, the slurry must be stabilized or mixed immediately prior to analysis. Slurry sampling GFAAS detection limits (DLs) are typically in the range of $10^{-2}$ to 1 part per million (pg absolute DLs). Precision (0.5–5%) and accuracy are also good, provided that proper guidelines for slurry preparation and instrument operation are followed, and samples are sufficiently homogeneous. An additional benefit of the technique is that matrix interferences are typically small; in fact, aqueous calibration standards are routinely used in the analysis of slurry samples. A limitation of slurry sampling GFAAS is that it is primarily a single-element technique, although continuum source and sequential atomic absorption spectrometry (AAS) systems have been developed. Furthermore, the linear range is typically less than two orders of magnitude unless alternative wavelengths, or some other means of reducing sensitivity (e.g., minigas flow during atomization), are used. In addition, some environmental samples have to be ground if the sample is not in the proper form or if the analyte is not homogeneously distributed. Care must be taken during the grinding process to avoid contamination of the sample or fractional distribution of the analyte.

1 INTRODUCTION

A growing awareness of the effects of trace elements on human health has fostered considerable interest in the analysis of a wide variety of environmental samples. In many instances, the analyses are directed towards identifying and quantifying elemental pollutants at high levels; however, the establishment of baseline levels is also important since this information can be used to reconstruct the past distribution of toxic pollutants on both local and global scales. The source and extent of contamination can then be more easily determined. Based on these considerations, analytical techniques used in environmental analysis must be capable of measuring elemental concentrations over a wide range of concentrations (parts per million to parts per trillion levels) in samples from all phases of the environment (air, ocean waters, soils, etc.). Accurate and reliable methods, which are cost-effective, easily implemented, and, perhaps most importantly, applicable to real world samples are required. Obviously, no single analytical technique is ideally suited for such a diverse range of samples; however, GFAAS is one of several techniques that have enjoyed widespread application in the field of environmental analysis. This is because the technique provides a relatively simple, inexpensive, and highly sensitive means of analysis. In addition, it offers some versatility since samples can be introduced to the graphite furnace in either solution or solid form.
Traditionally, samples have been introduced into the graphite furnace as solutions. This is particularly limiting since a large percentage of environmental samples are originally solids and require considerable processing to dissolve them prior to analysis. Over the past decade, solid sampling techniques for trace element determinations in environmental samples have increased in popularity owing to a number of potential advantages. The benefits include: reduced sample preparation time, since digestion procedures required for many environmental samples can be quite lengthy and complex; decreased analyte loss through volatilization prior to analysis or because of retention by an insoluble fraction of the sample matrix; reduced risk of sample contamination because less sample handling and fewer reagents are required; elimination of hazards associated with the use of acids and other corrosive reagents; and the potential for improved sensitivity since the sample is not diluted. Unlike nebulization techniques, GFAAS does not suffer significantly from particle size effects because it offers longer residence times and correspondingly higher atomization efficiencies. In addition, direct solids analysis by GFAAS provides unique information to the analyst with regard to the distribution of analytes in microamounts of sample and is particularly useful when only small quantities of sample are available for analysis.

The two principal methods for analyzing solids by GFAAS are to introduce the solid material directly into the furnace or to prepare a slurry or suspension, then inject the sample by using conventional liquid sampling methodology. Applications and the relative merits of both direct solid sampling and slurry sampling can be found in reviews by Bendicho and de Loos-Vollebregt(2) and Miller-Ihli.(3) For samples already in powder form (e.g., soils and sediments) or samples that can be efficiently ground, slurry sampling offers a number of advantages over direct solid sampling. Slurry sample introduction is straightforward and can be automated using commercial liquid autosamplers. This is advantageous for routine determinations and is a more reproducible means of sample introduction than weighing and transferring the sample, as is done with direct sample introduction. Slurry samples may also be “diluted” when the analyte concentration is too high to facilitate analysis in the linear range; however, consideration must be given to ensure that enough particles are still being sampled. With direct solids analysis, the sample can, in some cases, be diluted with graphite powder; however, this increases the risk of contamination. Both methods may take advantage of other methods for reducing sensitivity, such as choosing a less sensitive absorption line. This does, however, require additional optimization. Slurry sampling also allows for the addition of matrix modifiers directly to the slurry or suspension and calibration is typically easier, since aqueous standards can often be used. This is not the case for direct solid sampling, where matrix-matched calibration standards are routinely required to achieve accurate results.

The development and optimization of slurry sampling GFAAS methods for environmental samples requires consideration of a number of key issues. These include sample preparation protocols (e.g., grinding of samples and mixing of slurries), representative sampling of the slurry, matrix modification, optimization of furnace conditions, wavelength selection, and calibration. With careful consideration of these variables, slurry sampling GFAAS provides a unique and powerful tool for the analysis of environmental samples.

2 EVOLUTION OF SLURRY METHODS

Slurry sampling GFAAS has matured significantly since the first reports by Brady et al.(4,5) Obviously, one of the major concerns with this methodology is the necessity of introducing a representative sample aliquot into the furnace. This can only occur if the slurry is efficiently stabilized or homogenized during the time needed for sample introduction. Stabilization has been attempted with thixotropic agents, such as viscalex(6) and glycercol;(7) however, workers reported problems with reproducible pipetting because of material adherence to the exterior of the autosampler capillary and incomplete delivery of the sample with these high viscosity mediums. For this reason, sample homogenization using some form of physical agitation is preferred. Magnetic stir bar mixing(8,9) vortex mixing,(10,11) gas bubbling,(12,13) and ultrasonic agitation(14,15) have all been employed for slurry homogenization.

Slurry analyses utilizing magnetic stir bar mixing and manual pipetting are often reported in the literature. Although several workers have successfully used this methodology, it is limited because manual pipetting typically provides poorer precision than can be achieved with autosamplers. In addition, modern analytical laboratories require automated analyses for increased throughput. A system employing miniature magnetic stir bar mixing combined with an autosampler was developed for the analysis of food slurries.(16) A potential problem with using magnetic stir bar mixing, however, is that some samples (e.g., soils) contain particles that adhere to the stir bar because of their magnetic properties.(17)

Vortex mixing is effective in agitating slurry samples before analysis, but sample aliquots must be removed quickly and deposited into the furnace to avoid sedimentation of larger and/or denser particles that may occur. If a significant portion of the analyte is associated with these
particles, slurry GFAAS results will be systematically low. A major disadvantage of vortex mixing for slurry analysis is that it is not compatible with autosampler operation and is therefore of limited utility for routine determinations.

Homogenization of slurries using Ar gas bubbling has been described in the literature. A benefit of this methodology is that slurry mixing can be performed directly in an autosampler cup, thus allowing for automated analysis. The major disadvantage of gas bubbling is that the effectiveness is largely dependent on the particle size and density. Bendicho and de Loos-Vollebregt reported poor homogenization when using gas bubbling for glass slurries in the 82–341 µm range. Similarly, Lopez-Garcia et al. found it necessary to modify the suspension medium to minimize sedimentation of particles in the determination of Pb in a marine sediment sample.

Ultrasonic agitation with a compact probe is one of the most effective means of slurry homogenization. Ultrasound can effectively break up particle clusters, disperse solids, and increase wettability, leading to improved slurry stability. In addition, the ultrasonic action can increase the extraction of analyte into the aqueous phase of the slurry, which typically results in improved precision. Importantly, ultrasonic slurry mixing can be performed directly in an autosampler cup, allowing for completely automated operation. Of the mixing methods, only ultrasonic agitation has been employed in a commercial autosampler accessory (USS-100, Perkin–Elmer). The widespread acceptance of ultrasonic mixing for slurry preparation is evidenced by an international collaborative study in which 14 of the 16 collaborators used ultrasonic devices.

Representative sampling is obviously crucial to the success of slurry GFAAS in solids analysis; however, a number of additional issues must be considered when introducing solid material into the furnace. In comparison to solutions, solids pose a number of unique challenges in GFAAS analysis. Historically, these challenges have included high background levels associated with the solid matrix, difficulty in calibration, difficulty with refractory elements, build-up of residual material in the furnace, sample-dependent peak shapes, and particle size dependence. Undoubtedly, one of the most significant developments in the evolution of slurry GFAAS for the analysis of solids was the introduction of the stabilized temperature platform furnace concept (STPF). The STPF approach employs a platform furnace so that the analyte is atomized in a more isothermal environment. STPF also provides for matrix modification for analyte stabilization, rapid furnace heating, pyrolytically coated tubes to reduce chemical interferences, good background correction (such as the Zeeman effect), no gas flow during atomization, and integrated absorbance measurements for quantitation. Employing these conditions significantly improves the quality of slurry GFAAS analyses, allowing the technique to be routinely used for the determination of trace elements in solids. This was demonstrated in an international collaborative study where slurry GFAAS was used to analyze a variety of materials. It was concluded that the technique could be used for routine quantitative analysis, as long as the slurry analysis conditions were optimized and STPF conditions were employed.

3 OPTIMIZATION OF GRAPHITE FURNACE ATOMIC ABSORPTION SPECTROMETRY METHODS FOR SLURRY ANALYSES

3.1 Sample Grinding

Slurries are typically prepared from finely ground, powdered material. Unfortunately, not all samples received are in a form suitable for slurry preparation. As a result, grinding of the sample is necessary prior to analysis. There are a variety of grinding methods available, depending on the material hardness and required particle size. Although several workers have reported the need to work with relatively small particles for slurry GFAAS, accurate analyses have been reported using particles up to 300–400 µm. A general grinding method that is suitable for a variety of environmental materials is the use of a vibratory ball mill, such as the Spex Mixer/Mill (Spex, Metuchen, NJ, USA) or the Retsch Spectro Mill (K. Retsch Co., GmbH, Germany). These devices are available in an assortment of materials, such as stainless steel, agate, zirconia, tungsten carbide, boron carbide, and silicon nitride. To avoid contaminating the sample with the analytes of interest, it is extremely important to choose the proper grinding material. Stainless steel mills should be avoided if at all possible. The use of ceramics offers much better abrasion resistance and reduced likelihood of contamination. Common contaminants, and their relative levels, introduced from various grinding materials can be found in the Spex Handbook. Grinding times are dependent on the sample type, but typically are less than 30 min. For soils, Dobrowolski reported that 15 min of grinding (tungsten carbide ball mill) was sufficient to produce samples with 65–70% of the particles below 20 µm.

Wet grinding methods have also been used for reducing particle sizes in sediment and botanical samples. Grinding was done in this laboratory by adding beads (high purity zirconia, 2 mm in diameter) to the sample, which was in a polyethylene bottle, in a 10:1 weight ratio.
(beads : sample). Approximately 10–15 mL of water was added to the bottles and the mixture was shaken for 2 h. Significant levels of contamination were observed for Fe, Cr, and AI with this grinding method.

A method for grinding of biological and botanical samples, using Teflon® beads and polyethylene bottles, has been described. Samples (1–5 g) and Teflon® beads (12.7 mm in diameter) were placed in 125-mL polyethylene bottles with 15 mL of water (or 5% HNO₃). The mixture was shaken on a wrist action shaker for 20–60 min and then filtered through a coarse mesh (800 + µm) polyethylene screen to remove the Teflon® beads. Blanks for a range of analytes (Cu, Mn, Fe, Cr, Co, Pb, V, and Mo) were evaluated and indicated no significant contamination (<0.2 ppb). The data indicated that a 40-min grinding time was sufficient to produce samples with 85–90% of the particles less than 125 µm in diameter. The procedure was evaluated for slurry GFAAS analysis of several in-house control food samples and a National Institute of Standards and Technology (NIST) reference material (RM 8431 Diet) and the results compared favorably with the certified reference concentrations.

A common error when analyzing solid materials is to sieve them to provide a uniform fraction for analysis. While this might appear to be advantageous, it should be avoided if the goal of the analysis is to provide an accurate representation of the original solid. For example, if the analyte is associated with a particular particle size or type, the results will be biased if any of the sample is discarded.

### 3.2 Optimizing Slurry Preparations

Several factors must be considered when preparing slurries for GFAAS analysis. An obvious consideration for slurry preparation is the amount of material that will be injected into the furnace for analysis. This can be calculated using Equation (1):

$$M_F = \frac{M_S}{V_S} \times V_F$$

where $M_F$ is the mass injected in milligrams, $M_S$ is the mass of sample used to prepare the slurry in milligrams, $V_S$ is the volume of liquid (diluent) used to prepare the slurry in milliliters, and $V_F$ is the volume of the slurry injected into the furnace in milliliters. For a slurry prepared using 10 mg of solid sample in 1 mL of diluent, a typical 20-µL injection will introduce 200 µg of solid into the furnace. With some knowledge of the expected analyte concentration, one can optimize the slurry preparation, in accordance with conventional GFAAS protocol, to ensure that the concentration falls within the optimum range for calibration on the working curve. In addition, quantitative determinations should be performed at levels that are at least five times greater than the DL. The more material used to prepare the slurry for a fixed volume of diluent and/or the greater the extraction of analyte into the liquid phase of the slurry, the more representative the determined concentration will be to the concentration in the original sample. If analyte concentrations are too high to work in the optimum calibration range, the slurry can be diluted, smaller injections can be used, or GFAAS conditions can be modified to reduce the sensitivity (e.g. use alternative wavelength). The effects of slurry dilution and smaller injection volumes will be discussed shortly, whereas GFAAS wavelength selection and other means of reducing sensitivity will be discussed later in the article.

Although the concentration of analyte in the slurry is important, other interrelated factors of interest in optimizing slurry preparations include particle size, material density and homogeneity, diluent viscosity and density, maximum slurry concentration, and the distribution of analyte (solid to liquid) in the slurry. Holcombe and Majidi have characterized errors associated with slurry sampling, considering the volume of sample, the number of particles in the sample volume, and variations in the mass of individual particles (volumetric errors); as well as sedimentation errors, which are dependent on the particle size, density of the sample and diluent, and viscosity of the diluent. These workers concluded that volumetric errors can be minimized by working with small particles, concentrated slurries, and narrow particle size distributions; whereas sedimentation errors can be controlled by optimizing the sampling time window for a given matrix. The homogeneity of the material is a major consideration for slurry preparation. If the analyte is not homogeneously distributed in the solid material, grinding to a very small particle size (<10 µm) and increasing the number of particles in the sample will increase the likelihood that the measured concentration will be representative of the original material.

Calculating the number of particles in the injection volume is useful to ensure that sampling uncertainty is not a major source of imprecision. Assuming that the uncertainty associated with pipetting of the slurry is ±1 particle, and assuming that all particles contain representative amounts of the analyte, then a sample volume containing 50 particles would have a sampling uncertainty of less than 2%. The number of particles in the sample volume can be calculated based on the material density and particle size as given in Equation (2):

$$N_P = \frac{M_S}{\rho \times V_F}$$

where $N_P$ is the number of particles in the injection volume, $M_S$ is the mass of sample used to prepare the slurry in grams, $\rho$ is the density of the material in grams per cubic centimeter, and $V_F$ is the volume of the particle.

in cubic centimeters. Table 1 shows the minimum mass required to prepare a 1-mL slurry which will contain 50 particles in a 20-µL injection volume as a function of the material density and particle size. In all cases, the particles were assumed to be spherical. It is clear that the particle size has the largest influence on the required mass, since the volume has a cubic dependence on the particle radius. Densities for several common materials are provided in Table 2. To experimentally determine densities for powdered samples, a simple method has been described.\(^{15}\) Small autosampler cups (0.5 mL) were filled with material and the mass recorded. Then, the dead volume was determined by adding surfactant to fill the cup and recording the volume added. The mass of sample per corrected volume (known cup volume − dead volume) was then used to calculate the density of the solid.

Although working with concentrated slurries is beneficial in reducing volumetric errors and problems related to heterogeneity, there is a practical limit to the amount of material that can be pipetted. The volume of solid to volume of liquid in a slurry preparation (volume to volume ratio) can be so high that the autosampler cannot pipette such a viscous slurry. This ratio can be calculated from Equation (3):

\[
\frac{V_{\text{Solid}}}{V_{\text{Liquid}}} = \frac{M_S/\rho}{V_S}
\]

where \(M_S\) is the mass of sample used to prepare the slurry in grams, \(\rho\) is the material density in grams per cubic centimeter, and \(V_S\) is the volume of liquid used to prepare the slurry in cubic centimeters. A volume/volume ratio of 0.25 or less is typically acceptable for reliable and efficient pipetting.\(^{15,30}\) For a material with a density of 1 g cm\(^{-3}\), this corresponds to a slurry prepared with as much as 250 mg diluted to 1 mL. For materials of lower density, the maximum sample mass decreases linearly with density for a fixed diluent volume.

It is important to have some knowledge of the analyte distribution in the liquid and solid phases of the slurry to derive the maximum benefit from the slurry GFAAS technique. Particle size and the type of diluent influence the amount of analyte extracted into the liquid phase. In addition, different amounts of an analyte can be extracted depending on whether the analyte is occluded in the particle or if it is simply adsorbed on the surface of the particle. The use of acids in the diluent generally increases the analyte extraction efficiency. Nitric acid is most commonly used in the diluent; however, some workers\(^{12,13,31–33}\) have used hydrofluoric acid to increase the extraction efficiency for silicate-rich matrices, such as soils and sediments. Based on the authors’ experience, HNO\(_3\) concentrations between 2.5% and 5.0% result in approximately equal extraction efficiencies and have proven useful for a variety of sample types. The use of a more concentrated HNO\(_3\) solution does not significantly increase the extraction efficiency and leads to rapid degradation of the graphite tube. Extraction efficiencies are measured by preparing the slurries and determining the analyte content, then separating the solid and liquid phases by ultracentrifugation and measuring the analyte content of the liquid phase.\(^{24,25,34–35}\) Benefits of extraction are that it can lead to precision that approaches that obtainable with conventional liquid sample introduction and can also lead to analyses that are more representative of the original solid. It is important
to mention, however, that significant analyte extraction is not a requirement for accurate and precise analysis with slurry GFAAS.

The representative sample mass concept is useful in determining how much of the original sample is represented by a slurry analysis.\textsuperscript{23} The two extremes of the concept are where no analyte is extracted and where 100% extraction occurs. In the case of no extraction, the representative sample mass is only the amount of solid injected into the furnace. For a 2 mg of solid in 1 mL of slurry preparation and a 20-µL injection volume, this corresponds to 0.04 mg. If 100% extraction occurs, then the analysis of any volume of the sample is representative of the entire 2 mg of sample used to make the slurry. Most often, the amount of analyte extracted lies somewhere in between the two extremes. If it is assumed that the analyte is distributed homogeneously in the solid and that the percentage extracted into the liquid phase is representative of the sample mass dissolved, then the sample mass represented by slurry analyses can be calculated using Equation (4):

\[
M_a = V_F \times \frac{M_s}{V_S} \times (1 - f_x) + f_x \times M_s
\]  

(4)

where \(M_a\) is the representative sample mass in milligrams, \(V_F\) is the volume injected into the furnace in milliliters, \(M_s\) is the mass of sample used to prepare the slurry in milligrams, \(V_S\) is the volume of the slurry preparation in milliliters, and \(f_x\) is the fraction of analyte in solution.\textsuperscript{30} For the 2-mg slurry prepared in 1 mL, 5% analyte extraction would result in \(M_a = 0.14\) mg, 20% analyte extraction would result in \(M_a = 0.43\) mg, and 50% analyte extraction would result in \(M_a = 1.02\) mg. Representative sample mass values for three apparently equal mass to volume slurry preparations are given in Table 3. Provided that analyte extraction occurs to some extent, the benefit of using larger masses of sample to increase the amount of sample represented by the analysis is clearly evident. If extraction does not occur, no benefit is gained by increasing the sample mass. Improvements in measurement precision with increasing \(M_a\) values have been reported for various sample types.\textsuperscript{23,35} The representative sample mass concept also clearly illustrates the problem with discussing slurry preparations using terminology such as ‘0.2%’, which can be found in the literature. It should be noted that \(M_a\) is only an indicator of the extent of sample dissolution and resultant analyte extraction. Because calculations of \(M_a\) are based on the assumption that the analyte is homogeneously distributed and the percentage of analyte extracted is representative of the amount of solid dissolved, it is not an absolute quantity. For example, if the analyte is adsorbed on the surface of the solid, the extraction efficiency could far exceed the actual amount of material dissolved.\textsuperscript{23} A safe assumption is that the quantity of material represented by the analysis is not larger than the calculated \(M_a\) value.

Optimization of the slurry preparation obviously requires considerable planning to ensure that accurate and precise measurements are obtained. Each of the above considerations should be thoroughly examined. A sufficient quantity of material should be weighed out to prepare a homogeneous slurry, the analyte concentration should not exceed the optimum calibration range, a representative number of particles (≥50) should be injected into the furnace, and the slurry should not be too viscous to pipette. Analyte extraction should also be examined since this can lead to improved precision and a better representation of the original sample.

### 3.3 Slurry Preparation

Slurries should be prepared in accordance with the criteria discussed above. Weighing should be performed on an electronic microbalance. Static electricity can be problematic when weighing small particles, so an ionization source such as the Staticmaster (NRD Inc., Grand Island, NY) is recommended. Samples (typically 1–50 mg) can be weighed directly into autosampler cups to avoid problems that can result from the transfer of small quantities of sample. Autosampler cups should be acid cleaned to minimize trace element contamination and be made of Teflon®. Polypropylene cups might also be acceptable depending on the analytes of interest; however, polystyrene cups should be avoided since significant levels of Fe, Cu, Cr, Al, and Mg have been

observed after ultrasonic mixing. Although a variety of diluents have been used (e.g., HF for silicate-rich matrices), the authors have found a mixture containing 5% (v/v) sub-boiling distilled HNO₃ and 0.005% (v/v) Triton X-100 surfactant to be useful for a wide variety of sample types. Nitric acid facilitates the extraction of analyte into the liquid phase of the slurry; whereas Triton X-100 (Rohm and Haas registered trademark for octylphenoxypolyethoxyethanol, Sigma Chemicals, St. Louis, MO, USA) serves as a wetting agent and assists in particle dispersion. If particle coagulation is not problematic and/or analyte extraction is not desirable (e.g., in homogeneity characterization), distilled deionized water (18 MΩ) can be used as the diluent. In some cases, it might be desirable to prepare larger mass and/or volume slurry preparations. For these larger preparations, sample and diluent can be placed in polyethylene test tubes, avoiding the need for microweighing. Care must be taken with this approach, however, to ensure that a representative subsample is transferred to the autosampler cup for analysis. Vortex mixing has been shown to be effective in homogenizing the slurry while an aliquot is removed.

3.4 Slurry Mixing and Sampling

As previously discussed, several methods have been used for agitation of the slurry mixture. One of the most reliable means of slurry mixing is with an ultrasonic device, such as the automated Perkin–Elmer USS-100, combined with an autosampler (e.g., Perkin–Elmer AS-60). Handheld ultrasonic devices such as the Kontes Micro-ultrasonic cell disrupter (Vineland, NJ) or the Sonics and Materials Model VC-40 (Danbury, CT) can also be used. The power output of these devices should be adjusted so that the slurry is vigorously mixed with a rolling action, but not so high that splattering occurs. The power output of these devices is quite variable and tuning is somewhat subjective; therefore, no exact condition can be provided. In general, the 40-watt mode of operation is used and the power is adjusted to 60–80%. Mixing times of 15–25 s are generally adequate for all materials. If the analyte is easily extracted into the liquid phase, even shorter mixing times can be used. One might expect that shorter mixing times would be required for low-density materials but that is not the case. Because particles with densities less than 1 mg cm⁻³ tend to float, ultrasound is necessary to wet the particles and keep them dispersed in the slurry. The use of a surfactant, such as Triton X-100, is beneficial for the same reasons. Since the slurry technique can tolerate particle sizes up to several hundred microns, it is advisable that the diameter of the autosampler sampling orifice be checked to ensure that it is sufficiently large. In the authors’ laboratory, the standard AS-60 tubing (approximately 300 µm in diameter) was replaced with Teflon tubing which was 810 µm in diameter.

Although a particular slurry might be sufficiently homogenized during ultrasonication, it is important to consider the influence of particle sedimentation on the analytical results since a finite time exists between the end of the mixing procedure and the pipetting of sample. Potential errors associated with sedimentation can be predicted based on Stokes’ Law. The settling velocity for sample particles can be calculated from Equation (5):

\[ v = \frac{2gr^2(p_1 - p_2)}{9\eta} \]

where \( v \) is the settling velocity in centimeters per second, \( g \) is the acceleration due to gravity (981 cm s⁻²), \( r \) is the particle radius in centimeters, \( p_1 \) is the density of the solid in grams per cubic centimeter, and \( p_2 \) is the density of the suspending medium in grams per cubic centimeter, and \( \eta \) is the viscosity of the medium in grams per centimeter second. It is clear from this expression that the sedimentation rate is reduced for smaller particles, when the particle and medium densities are closely matched, and when a high viscosity medium is used. As was previously mentioned, a major problem associated with using high-viscosity mediums, such as glycerol or viscalex, is the inability to pipette them efficiently. Fortunately, it is not necessary to match densities or use high-viscosity mediums, since the sampling depth can be varied in order to remove a representative portion of the slurry. For the 5% HNO₃ + 0.005% Triton X-100 diluent described above, which has a density of 1.02 g cm⁻³ and a viscosity of 0.01002 g cm⁻¹ s⁻¹, it was demonstrated that a sampling depth of 7.2 mm or greater was required to remove a representative sample of a high-density (\( \rho = 2.6 \) g cm⁻³) glass slurry. Sampling depths of 2.5 mm or less precluded the sampling and measurement of particles 50 µm or greater (78% analyte recovery); whereas a depth of 7 mm did not allow for the sampling and measurement of particles 80 µm or larger (92% analyte recovery). Sampling too deep into the autosampler cup also proved problematic because of the build-up of particles in the conical-shaped bottom of the autosampler cup. With knowledge of sample particle sizes and density, the required sampling depth can be easily calculated to ensure representative sampling of the slurry. For high-density materials, it might be advisable to grind the sample to reduce the particle size and subsequently reduce the settling velocity.

3.5 Operating Conditions

Successful slurry determinations depend on proper selection of GFAAS operating conditions. Typically, operating conditions similar to those used with conventional acid
diigests can be employed. The use of STPF conditions as described by Slavin et al.\textsuperscript{20,21} is particularly useful because it facilitates the analysis of slurry samples using aqueous calibration standards. This greatly enhances the slurry GFAAS methodology, making it a suitable alternative to conventional acid digests.

As an example, typical conditions for the determination of Cu in a sediment sample are given in Table 4. Wavelength selection is dependent on the expected analyte concentration in the slurry preparation. For high analyte concentrations, less-sensitive nonresonance wavelengths should be used to extend the working range, particularly where there are concerns about the number of particles being injected into the furnace for analysis. Alternatively, the use of a minigas flow (typically 30–300 mL min\textsuperscript{-1}) during atomization has been successfully used to reduce analyte sensitivity in some cases (see for example Lopez-Garcia\textsuperscript{33} and Belarra\textsuperscript{36}); however, this is generally not recommended since it can lead to non-isothermal atomization conditions.\textsuperscript{19,22} A more detailed discussion on minigas flows and other means of sensitivity reduction will be provided later.

Other essential aspects of the STPF concept are platform atomization, fast heating, good background correction, the use of integrated absorbance measurements for quantitation, and, if necessary, the use of a matrix modifier. Platform atomization should be used for all but the most refractory elements since more isothermal atomization conditions are achieved. Because of the large amount of solid injected into the furnace and subsequently large background signals, good background correction such as Zeeman or Smith–Hieftje is essential. The use of integrated absorbance measurements for quantitation eliminates problems associated with matrix dependent peak shapes. This is important if aqueous standards are to be used for calibration of slurried materials.

Matrix modification can be useful in stabilizing analytes during the charring step and in eliminating or reducing matrix effects. The use of a traditional matrix modifier (e.g. palladium or magnesium nitrate) is straightforward with slurry GFAAS, since the liquid modifier can be added directly to the slurry preparation. The amount of modifier will typically be larger than those used with liquids because of the larger masses of material in the furnace. Much of the work with chemical modification for slurry GFAAS has been carried out in order to stabilize highly volatile analytes such as Cd,\textsuperscript{34,37,38} Pb,\textsuperscript{18,16,19,37–39} Se,\textsuperscript{32,40} and Hg.\textsuperscript{9,26} For samples with a high organic content, air/oxygen ashing can be used to remove carbonaceous material prior to atomization.\textsuperscript{23,41,42} This not only prevents residue from building up inside the furnace, but can also reduce background levels and minimize matrix effects. The addition of hydrogen peroxide to the slurry has also been used for the removal of carbonaceous material in the furnace.\textsuperscript{23,45} For samples with a high silica content, the use of HF in the slurry diluent has been reported.\textsuperscript{19,12,31–33} Some of the reported benefits of using HF are increased analyte extraction, the removal of silicon (as SiF\textsubscript{4}) during the heating cycle which minimizes damage to the graphite tube and allows larger masses to be injected, and reduced matrix suppression effects because of the partial digestion of the matrix.\textsuperscript{19}

The need for a matrix modifier is determined from systematic optimization of the drying, charring, and atomization conditions. It is important that these conditions are optimized for each sample type, since the matrix can significantly affect the volatilization characteristics of the analyte. In some instances, fast-temperature programs, in which the conventional drying and ashing steps are replaced by a single modified drying stage, have been used successfully.\textsuperscript{19,32,33,43–45} The major benefit of fast-temperature methodology is a significant reduction in analysis time. It has been used for the determination of As, Pb, Tl, and Se in coal and coal fly ash;\textsuperscript{45} Pb,\textsuperscript{33,44} Cd,\textsuperscript{33} Se,\textsuperscript{32} and Hg,\textsuperscript{9,29} and Tl\textsuperscript{33} in soil; and Pb and Cd in vegetables.\textsuperscript{45} Although chemical modifiers are often unnecessary since a conventional ashing stage is not used and the risk of analyte loss is small, they may be useful in delaying atomization of the analyte in the furnace until more isothermal conditions are achieved.\textsuperscript{33}

\(m_o\) is the characteristic mass (mass of analyte producing an integrated absorbance signal of 0.0044 s) 20 μL injection volume.
### Table 5 Recommended procedure for ultrasonic slurry GFAAS determinations

1. Grind the sample, if necessary, to produce a powder
   - particle sizes up to 300–500 μm may be acceptable
   - grinding methods: mortar grinding and Teflon® beads and polyethylene bottles (biological and botanical samples); grinding, pulverizing, or vibratory ball mills
   - minimize contamination risks (no stainless steel)
   - do not sieve samples
2. Optimize slurry preparations
   - calculate minimum mass required for analysis based on particle size and density (>50 particles) and select appropriate analytical wavelength
   - factors of interest include homogeneity of solid, distribution of analyte in solid, sample density, particle size, diluent viscosity and density, and analyte partitioning in the slurry (calculate representative sample mass)
   - if analyte is heterogeneously distributed in the solid, strive for very small particles (<10 μm)
   - calculate the (volume of solid/volume of diluent) to ensure the ratio is ≤0.25
3. Prepare slurries for analysis
   - weigh samples using electronic microbalance (avoid static with ion source)
   - 1–50 mg of ground material may be weighed directly in a Teflon® autosampler cup
   - Add 1–1.5 mL of diluent (5% sub-boiling distilled HNO₃ containing 0.005% Triton X-100®)
   - slurries may be prepared using larger masses and/or volumes if conditions require
4. Ultrasonic slurry mixing and sampling
   - power output to ultrasonic probe should be adjusted to provide good mixing (typically 60–80%)
   - mix time of 15–25 s
   - consider particle sedimentation and adjust sampling depth accordingly
5. GFAAS conditions
   - wavelength selection based on analyte concentration in slurry
   - less sensitive, nonresonance lines may be useful for high analyte concentrations
   - GFAAS conditions should be systematically optimized (char and atomization temperatures)
   - STPF conditions should be employed
   - oxygen ashing may be useful for removal of carbonaceous material, HF may be useful with high-silica-content matrices
   - quantitation is accomplished using aqueous standards and peak area measurements
   - the use of a matrix modifier and char step may not be necessary
6. Number of determinations
   - typically five readings of each of five slurry preparations are adequate when analyzing an unknown sample
   - data should be reviewed to determine if measured concentrations suggest a dependence on sample weight or sample heterogeneity

Without detailed knowledge of the homogeneity of the material it is difficult to know how many subsamples should be weighed out and prepared as slurries to provide a representative measure of the mean analyte concentration in the original sample. In addition, the influence of analyte extraction into the aqueous phase of the slurry significantly affects the mass of material represented by the slurry measurement. For this reason, it is important to consider what information is needed from the analysis. If the objective is to gain information on the homogeneity of the material at the microgram level, then analyte extraction should be minimized (no acid in diluent) so that the analysis is representative only of the amount of solid injected into the furnace. Homogeneity characterization levels (microgram to milligram) are established by the representative sample mass.

For high-accuracy measurements of bulk analyte concentrations, an analysis of variance (ANOVA) can be performed to determine the optimum number of slurry preparations and replicate analyses. Based on practical experience, it is typically found that starting with 3–5 replicate readings of 3–5 slurry preparations is sufficient to determine if additional readings are necessary and if the slurry GFAAS technique is suitable for analyzing the sample of interest. In addition, it is advisable that the mass of material used to prepare the slurry be varied to determine if the measured concentrations suggest a dependence on sample mass or indicate sample heterogeneity. If heterogeneity is evident, it might be useful to grind the sample to reduce particle sizes and/or use a larger sample mass. The mass of material used to prepare the slurry must take into account each of those factors (e.g. particle size, density, diluent volume, etc.) previously discussed.

The recommended procedure for slurry GFAAS determinations is outlined in Table 5.

### 4 ENVIRONMENTAL APPLICATIONS

Slurry sampling GFAAS is well suited for the analysis of a range of environmental samples. Numerous applications of the technique for the determination of trace elements in environmental matrices can be found in past reviews or in annual Atomic Spectroscopy Updates featured in the Journal of Analytical Atomic Spectrometry. In this section, several of the most recent applications of slurry GFAAS for environmental analyses will be described and the performance of the technique will be discussed.

#### 4.1 Characteristic Masses, Detection Limits and Ranges

The concept of characteristic mass \( m_c \) in AAS provides a measure of the sensitivity of the determination for a

$^a$ Characteristic mass (mass of analyte producing an integrated absorbance signal of 0.0044 s).
$^b$ Calculated absolute DLs are given in parentheses.

particular analyte. It is defined as the mass of analyte that produces an integrated absorbance signal of 0.0044 s. The DL, on the other hand, is defined as the smallest amount of analyte that can be detected with some stated level of confidence. It is generally defined as the concentration (or mass) of analyte that produces a signal that is three times greater than the standard deviation of replicate blank measurements. Since the DL considers the limiting noise source associated with the measurement of a particular analyte, it is useful in comparing different analytical techniques for determining one analyte or for determining several analytes by one technique.

Recently reported characteristic mass values and DLs for the determination of analytes in a variety of environmental samples by slurry GFAAS are given in Table 6. Characteristic masses and DLs are dependent on several factors including the design of the furnace, atomization conditions, absorption wavelength, background correction method, and the use of matrix modifiers. Additionally, both the characteristic mass and the concentration DLs are dependent on the amount of material used to prepare the slurry and the amount of material injected into the furnace. They do not, however, necessarily increase linearly with the mass of sample injected into the furnace. Reporting of the absolute (or mass) DL is often useful for comparison purposes since this takes into account the amount of sample used for the analysis. Absolute DLs have been calculated and included in Table 6. Characteristic mass values and absolute DLs are in the 1–100 pg range for most elements.

As previously mentioned, a limitation of GFAAS is the limited analytical range. For a given wavelength, the analytical range is generally only two or three orders of magnitude above the DL. For this reason, it is often necessary to ‘dilute’ the slurried samples or modify the GFAAS analytical conditions. The feasibility of diluting the slurry depends on the homogeneity of the material, the amount extracted into the liquid, and the number of particles that will be injected into the furnace. A preferable alternative is to use less-sensitive, nonresonance absorption wavelengths to extend the analytical range. Although this method has been widely used with excellent success, not all elements exhibit nonresonance lines with acceptable analytical characteristics. In these cases, the use of a minigas flow (30–300 mL min$^{-1}$) during the atomization step might be useful in reducing sensitivity.

significantly affected, the reliability of this approach must be confirmed for each matrix and analyte studied.\(^{(19,22)}\)

4.2 Analytical Performance – Benefits and Limitations

Table 7 lists several applications of slurry GFAAS for the analysis of environmental materials and includes some comments on mixing methods, matrix modifiers, and calibration procedures used. Most workers have developed methodology that allowed for aqueous calibration. However, in some cases, standard additions were necessary to achieve accurate results.\(^{(25,26,33,34,37,39)}\) The need for standard additions calibration was likely due to incomplete removal of the sample matrix or the presence of interfering atomic or molecular species. Accuracy of slurry GFAAS measurements is also dependent on the homogeneity of the sample, particle sizes, amount of sample used in the slurry preparation, and the extent of analyte extraction. For this reason, it is advisable to make multiple preparations using different masses of sample to determine the minimum mass required to achieve consistent measured concentrations. As previously discussed, reducing particle sizes by grinding might also be beneficial for improving the homogeneity of the sample. Precision is similarly affected by particle size, homogeneity of the sample, mass of slurry preparation, and extent of analyte extraction. When analyzing homogeneous samples under optimum analytical conditions, the slurry sampling GFAAS technique can be expected to provide accuracies of ±5% and measurement relative standard deviation (RSD) values of 5% or less.
In addition to the ability to obtain highly accurate and precise measurements with slurry sampling GFAAS, the technique offers several additional benefits. These include the often mentioned benefits associated with solids analysis techniques, such as reduced contamination, decreased sample preparation times, and reduced likelihood of analyte loss during sample preparation or because of retention by an insoluble fraction. Other benefits of the GFAAS technique are the simplicity and relatively low cost of the instrumentation as well as the ability to characterize solid materials on the µg to mg level. These attributes make slurry sampling GFAAS a powerful technique for the determination of trace analytes in environmental samples. However, the technique does have some limitations.

One of the major limitations of GFAAS is that it is primarily a single-element technique; however, multielement systems based on continuum sources (simultaneous) or multiple HCLs (sequential) have been developed. Sequential systems are limited by relatively slow duty cycles, making them less than ideal for use with transient GFAAS signals. Although not commercially available at present, continuum sources combined with fast multichannel detectors might prove useful in the future for multielement slurry GFAAS analyses. Using a prototype simultaneous multielement atomic absorption spectrometer with a continuous source (SIMAAC) with photomultiplier tubes as detectors, it has been reported that up to seven elements could be simultaneously determined with an average accuracy of 100 ± 12% and an average precision of <10% RSD. Obviously, compromise conditions must be used when measuring several elements at once. Char temperatures should be low enough to avoid loss of the most volatile analyte, whereas atomization temperatures should be high enough to ensure that the most refractory element is atomized.

Conventional slurry GFAAS analyses require careful, systematic optimization of instrumental and sampling parameters for each analyte and matrix of interest. Obviously, this can be a time-consuming process and careful consideration should be given to what type of information is desired from the analytical measurement. The small sample masses injected into the furnace that are beneficial for homogeneity characterization might lead to unacceptably poor precision when bulk concentration of the analyte is the desired objective. Sample heterogeneity can be particularly problematic when dealing with complex environmental samples. The limited analytical range associated with AAS measurements can also prove problematic when analyzing samples with very different analyte concentrations. Although alternate wavelengths or minigas flows can be used to reduce sensitivity, these require additional optimization.

### 4.3 Comparison of Sample Types

As evidenced in Table 7, slurry sampling GFAAS has been used for the determination of a variety of elements in numerous environmental samples. In this section, some of the issues related to specific sample matrices will be discussed. Particle size plays an important role in slurry GFAAS analyses. Several workers have reported the need to work with relatively small particles (<50 µm) for accurate and precise analyses; however, it has been demonstrated in the authors’ laboratory that good results could be obtained for samples with particle sizes up to 500 µm in diameter. The composition and homogeneity of the matrix, as well as the percentage of analyte extracted, largely dictates what range of particle sizes can be used for the analysis. For samples that are easily ashed, such as biological materials, larger particle sizes can be tolerated. For samples that are more refractory in nature, such as geological materials, it might be necessary to use small particles for the analysis to ensure complete vaporization of the particle and/or complete release of the analyte. Even for a highly volatile element such as Hg, it has been reported that particle sizes of less than 20 µm were necessary to ensure the complete release of Hg from marine sediment samples.

Another key point in determining what particle sizes can be used for analysis is the stability of the slurried sample. In section 3.4, the effect of particle sedimentation on the accuracy of slurry GFAAS measurements was discussed. For higher-density materials (see Table 2), it is imperative that the sampling depth be great enough to ensure that a representative aliquot of the sample is removed for injection into the furnace. Because a finite time can exist between the end of the mixing step and pipetting of the sample (e.g. with automated ultrasonic mixing systems), and autosampler cups are of limited depth, it might be necessary to reduce particle sizes for high-density materials in order to minimize the rate of sedimentation and allow for representative slurry sampling.

Because of the relatively large amount of solid material being vaporized in the furnace, matrix effects can significantly affect the quality of slurry GFAAS measurements. The presence of organic material, not completely removed during the charring step, affects the volatility of some elements, increases background levels, and leads to the build-up of carbonaceous material in the furnace. These problems are most significant for biological matrices, such as plants and foods. However, appreciable levels of organic material can be found in many types of soil as well. To alleviate these problems, matrix modifiers can be used to stabilize volatile elements during furnace heating and good background correction methods (e.g. Zeeman or Smith–Hieftje) should be employed. An effective method
for removing carbonaceous material and thus avoiding its deleterious effects has been the use of an oxygen or air ashing step in the furnace program.\(^{23,41,42}\) Hydrogen peroxide added to the slurry diluent has also been reported to be useful for this purpose.\(^{37,43}\)

Samples high in silicate have been shown to seriously affect analyte signals in slurry GFAAS. In work with glass samples, Bendicho and de Loos-Vollebregt found that after 50–100 firings of the furnace absorbance signals decreased and precision became worse.\(^{12}\) In addition, rapid deterioration of the graphite tube has been reported when analyzing high-silicate matrices due to the formation of silicon carbide at high temperatures.\(^{33}\) In order to avoid problems related to graphite tube degradation and matrix suppression effects, silicon can be removed by addition of HF to the slurry diluent.\(^{9,31–33}\) Silicon is volatilized as SiF\(_4\) during the furnace heating cycle. In addition, HF increases analyte extraction and leads to a decrease in particle sizes because of partial dissolution of the matrix.\(^{33}\) Fluoride compounds, such as NaF\(^{31}\) and NH\(_4\)F,\(^{54}\) have also been studied for the removal of silicon during furnace heating, but did not significantly decrease the amount of silicon prior to atomization. Because of the highly corrosive and toxic nature of HF, extreme caution should be exercised when using this acid. In addition, ultrasonic mixing should not be used to mix slurries containing HF because of damage caused to the titanium probe. For this reason, other methods for slurry agitation must be employed or alternatively, HF could be pipetted separately into the furnace (just as a matrix modifier might be added). A problem reported with the use of HF is the violent reaction of this acid with fine silica particles, which resulted in spattering and loss of analyte.\(^{54}\) To avoid this problem, a low temperature (60°C) reaction step lasting 3 min was used prior to drying and charring of the sample. Several other elements (B, As, Sb, and Ge) form volatile fluorides and may be lost along with silicon. However, their volatilities are highly dependent on oxidation states, which are controlled by a combination of acids used and sample composition.\(^{55}\) Workers have reported difficulties in the determination of As in soils and sediments using HF due to analyte loss during the heating cycle.\(^{31}\) The problem was alleviated by neutralizing the slurry with sodium hydrogen carbonate prior to injection of the sample into the furnace.

5 COMPARISON WITH OTHER DIRECT ANALYSIS METHODS

Numerous spectroscopic methods have been utilized for the elemental analysis of environmental samples; however, no single technique is capable of addressing all analytical needs. For this reason, it is essential that the analyst understand the benefits and limitations of specific techniques in order to choose a suitable method for a particular analytical measurement. In this section, several spectroscopic methods will be discussed and the performance of these methods will be compared with slurry GFAAS for the analysis of environmental samples.

The benefits associated with direct solids analysis have already been discussed. Briefly, these include reduced analysis times because samples can be analyzed with little to no sample preparation, reduced risk of contamination from reagents, reduced likelihood of analyte loss during dissolution procedures or because of retention by an insoluble portion of the sample, potential for improved sensitivity since the sample is not diluted, and the selective analysis of microamounts of solid. A wide variety of methods can be used to analyze solid environmental samples, including X-ray fluorescence (XRF) and total-reflection X-ray fluorescence (TXRF), electrothermal vaporization inductively coupled plasma atomic emission spectrometry (ETV/ICP/AES), and electrothermal vaporization inductively coupled plasma mass spectrometry (ETV/ICP/MS) laser ablation inductively coupled plasma atomic emission spectrometry (LA/ICP/AES), and laser ablation inductively coupled plasma mass spectrometry (LA/ICP/MS) laser induced breakdown spectrometry (LIBS), direct current arc atomic emission spectrometry (DC Arc/AES), glow discharge mass spectrometry (GDMS), both laser ablation/laser excited atomic fluorescence (LA/LEAFS) and electrothermal atomization/laser excited atomic fluorescence (ETA/LEAFS), electron microprobe analysis (EMP) and X-ray microprobe analysis (XMP), and neutron activation analysis (NAA) and instrumental neutron activation analysis (INAA) techniques. In this section, some of the more commonly used techniques, or techniques with considerable potential for direct analysis of solid environmental samples, will be discussed. In particular, these are XRF and TXRF, ETV/ICP/AES, ETV/ICP/MS, LA/ICP/AES, LA/ICP/MS, and LIBS. Typical analytical characteristics of these techniques are summarized in Table 8. XRF has been widely used in the field of environmental analysis. It is a nondestructive, multielement technique capable of simultaneous detection of elements with atomic numbers 11 < Z < 92. It is particularly useful for contamination monitoring, and portable devices capable of in situ measurements have been developed for this purpose.\(^{56}\) The XRF technique, however, suffers from relatively poor DLs, making it unsuitable for trace analysis. In addition, matrix effects are often problematic unless very thin samples or residues are being analyzed. Significant improvements in terms of both absolute DLs and the occurrence of matrix effects can be achieved.
Using TXRF, this technique is suitable for very small sample amounts (<100 µg) with thicknesses ranging from 10 nm–10 µm depending on the matrix. Samples must be placed on polished carriers to ensure the absence of matrix effects. Calibration is typically performed by spiking the sample with an internal standard. DLs are in the picogram range (µg g⁻¹) with thicknesses ranging from 10 nm–10 µm depending on the matrix. Samples must be placed on polished carriers to ensure the absence of matrix effects.

ETV/ICP/AES and ETV/ICP/MS are becoming increasingly popular for the direct analysis of solid samples. Issues related to preparation of the sample and representative sampling of the solid are identical to those previously discussed for GFAAS. In ETV techniques, the graphite furnace is used to vaporize the sample before it is transported into the ICP source. Separation of the vaporization step and analyte excitation (for AES) or ionization (for MS) can lead to improved analytical performance since each process can be independently optimized. Because they are multielement techniques, with high sensitivity and wide linear dynamic ranges (5–7 orders of magnitude), ETV/ICP/AES and ETV/ICP/MS are powerful methods for the analysis of environmental samples. DLs for ETV/ICP/AES are generally poorer than those obtained with GFAAS; however, ETV/ICP/MS DLs are, in general, comparable or better (sub picogram levels, ng g⁻¹ in solid) than GFAAS. ICP/AES offers simultaneous multielement analysis, whereas ICP/MS relies on scanning of the quadrupole mass analyzer and provides sequential multielement analysis. This means that with ICP/MS, only about five elements can typically be measured during an analysis because of the transient nature of the ETV signal. In addition to providing DLs that are one hundred or more times better than ICP/AES, ICP/MS spectra are much simpler and spectroscopic interferences are less problematic than with ICP/AES. This is particularly advantageous when analyzing complex environmental matrices. Another important benefit of mass spectrometric detection is that it allows the determination of isotope ratios.

The suitability of ETV/ICP/MS for very sensitive and accurate analysis of a variety of environmental samples is evidenced by a large number of applications of the technique. Most workers have reported the need to use the method of additions to obtain satisfactory results with this technique, most likely because of differences in analyte transport between aqueous standards and solid samples or because of matrix effects in the ICP/MS. It has been demonstrated that the use of a physical carrier (e.g. Pd) or removal of part of the solid matrix (e.g. organics by oxygen ashing) can be useful in minimizing differences in analyte transport efficiency, thereby allowing the use of aqueous standards for quantitation. Signal suppression due to space charge effects can also be problematic, especially when large amounts of solid are introduced into the ICP/MS. Removal of matrix components prior to vaporization can be used to reduce space charge effects. A very powerful quantification method available with ICP/MS techniques is isotope dilution. Since another isotope of the same element represents the ideal internal standard for that element, isotope dilution should provide accurate results even in the presence of matrix effects, instrument instability, and fluctuations (or loss) of analyte in vaporization and transport processes. Successful application of isotope dilution to ETV/ICP/MS measurements has been reported for the determination of Cd and Se in biological and environmental samples and Cu, Cd, and Pb in sediments.

Laser sampling techniques, such as LIBS and LA/ICP/MS are becoming increasingly popular for direct solids analysis, since little to no sample preparation is required. Samples can be analyzed in either compact or

¹ DL in the solid.
⁶ Requires assumption that laser produces representative sampling; laser techniques, in general, require special consideration for quantitation and are more prone to matrix effects.
⁵ Isotopic selectivity.

Table 8 Comparison of techniques for direct solids analysis
powdered form. The modest spatial resolution (~10 µm lateral and ~1 µm in-depth) achieved with laser sampling can also provide the analyst with information on the distribution of elements in a sample. One of the limitations of laser sampling is that laser–material interactions are complex, which results in an unknown quantity of ablated material with a composition that may or may not be representative of the bulk material.\textsuperscript{(70)} For this reason, internal standardization and matrix-matched standards are typically required to produce accurate results. The use of ultraviolet lasers, rather than infrared, has been shown to be beneficial because of improved spatial resolution, minimization of selective vaporization, and enhanced ablation efficiencies.\textsuperscript{(70,71)} LIBS provides rapid multielement analysis with DLs for most analytes in the μg g\textsuperscript{-1} range. In addition to being a useful laboratory technique, compact LIBS systems have been developed for on-site analysis.\textsuperscript{(72,73)} LA/ICP/MS offers improved DLs compared to LIBS (100 times or more) and greater freedom from matrix interferences because the sampling and excitation (ionization) steps are separated and can be independently optimized. In addition, spectral interferences are less problematic with mass spectrometric detection, as previously discussed for ICP/AES and ICP/MS. Although calibration remains an impediment to the widespread applicability of LA/ICP/MS, alternatives to matrix-matched standardization, such as the use of fused-glass beads\textsuperscript{(74)} or dual-sample introduction systems,\textsuperscript{(75–77)} have been described for calibration purposes and the future of the technique appears to be very promising.

No single technique is capable of addressing the wide range of analytical needs. In choosing the most appropriate method for an analysis, careful consideration should be given to a number of issues, including the type of information required from the analysis (e.g., bulk or microanalysis), detection capabilities, number of elements to be determined, cost, and sample throughput. As a general rule, the simplest method that meets analysis requirements should be used. In many cases, considerable benefits can be gained by using one or more complementary techniques for analysis.

6 FUTURE EXPECTATIONS

The relative maturity of slurry sampling GFAAS for routine analysis of environmental materials has been demonstrated in an international collaborative study.\textsuperscript{(19,22)} Since slurry sampling is ideally suited to the analysis of samples that are already in powdered form, it will continue to be widely used for the analysis of soils and sediments. Many other solid materials are well suited for slurry analysis, especially botanicals and food samples, since they can be easily ground with minimal risk of contamination. The use of ultrasonic mixing and autosampler pipetting has made sample introduction routine and reliable; in fact, the major source of imprecision in slurry GFAAS measurements is sample heterogeneity. For this reason, the technique is quite useful for homogeneity characterization of samples at the microgram to milligram level.

Relative DLs obtainable with slurry GFAAS are excellent, with only ICP/MS techniques providing better values. Although multielement ETV/ICP/MS and LA/ICP/MS appear to be quite promising, these techniques are not at the stage where they can compete with GFAAS for routine analyses, especially when multielement data are not required. Matrix effects are more problematic with ICP/MS and the instrumentation is more complex and expensive. It is likely that each of the techniques will continue to prosper and that choice of one technique over the other will be decided based on the required sensitivity, number of elements to be determined, and cost. The development of commercial, continuum source AAS instruments may greatly improve the applicability of slurry GFAAS for multielement, environmental analyses.

Instrumental methods play an important role in the analysis of soil material. Soil is composed of mineral, organic, water, and air components. Analytical methods are required that characterize the fitness or quality of soils to perform various functions, such as providing a medium for plant growth, recycling waste products, and regulating and storing water, energy, and nutrients. The objective of this article is to describe the basic concept and approach to laboratory analysis of soil, and to outline the application of techniques used in the analysis of soil quality properties. Emphasis is placed on soil sampling and sample preparation, followed by a description of the possible instrumental methods available for the analysis of the chemical, biochemical, and physical properties of soil.

1 INTRODUCTION

Soils serve as an interface between aquatic, atmospheric, and terrestrial ecosystems. In this capacity, the soil provides important functions such as supporting plant and animal life, providing a sink and source of biogenic energy and nutrients, partitioning the flows of energy and water, regulating the solubility of toxic elements, providing a sink and source for greenhouse gases (e.g. CO₂, N₂O, CH₄) and mitigating their accumulation in the atmosphere, and acting as an environmental buffer. Soil forms at a relatively slow rate, so should be considered a nonrenewable natural resource.

Soil is composed of interacting mineral, organic, water and air components and has strong biological features. Knowledge of the chemical, physical, and biological properties of soil can only be fully obtained by recourse to analytical methods. The need for soil analytical methods is underlined, by both the scientific community and the general public, in the ongoing concern with soil and environmental quality protection, and the sustainability of the biosphere. Analysis of soil material in the laboratory can provide information on soil properties, but it should be realized that some of these properties may not be always equivalent to the same property measured in situ, as the removal of the material will also remove the influence of adjacent soil and the ambient environment.

Soil is used for various purposes, such as a medium for plant growth, for recycling numerous waste products, and as a construction material. Thus, methods are required that can characterize soil material for a specific use or purpose. The wide range of disciplines that have an interest in soil analysis (e.g. agriculture, forestry, earth sciences, civil engineering, and environmental science) underlines the need for the continued development of analytical and testing methods. This article describes the basic concept.
and approach to laboratory analysis of soil material, and provides a select description of instrumental analysis of the chemical, physical, and biological properties of soil, with an emphasis on instrumental methods of analysis for soil quality attributes.

1.1 Soil Chemical Properties

Soil can be viewed as a three-phase system of solid, liquid, and gaseous components in an ever-shifting equilibrium. Chemical analysis can involve characterization of all three phases. The solid phase consists of various soil minerals and organo-mineral complexes. Generally, most analysis is concerned with specific constituents of the solid and liquid phases that have importance for a certain soil function (e.g. soil as a medium for plant growth). The interface between the solid (generally clay sized, <2 µm, secondary phyllosilicate minerals) and liquid phases is usually a net-negatively-charged particle surface surrounded by a diffuse layer of hydrated counterions merging into the soil solution or liquid phase. In many cases, the chemical composition of both the diffuse layer and the soil solution is of interest. Analysis of the soil air or atmosphere is often conducted to determine soil aeration and the presence of physiologically active gases such as ethylene, toxic gases, and radiatively active gases. For plant growth studies, the availability of soil nutrients and chemical elements that impact on plant productivity are a major concern for “soil test” determinations.

1.2 Soil Biochemical Properties

Soil is a dynamic medium for many organisms that transform and cycle organic materials (i.e. mainly plant residues) and chemical elements. These chemical processes result in the formation of organic compounds that are important for the functioning of the soil. Many of these biochemical compounds and their related properties can be measured and characterized. Although soil is a three-phase system of solid, liquid, and gaseous components, it also contains living organisms or a biotic component. Soil biochemical properties are related to the activities of these organisms and the biochemical substances they produce. The importance of microbes to soil ecology is reflected in the numerous analytical techniques available in the area of soil microbiology.\(^1\)\(^-\)\(^3\)

1.3 Soil Physical Properties

Soil physics deals mainly with the properties of the soil solid phase, especially the framework it supplies for the storage of water and the movement of water and air. Physical properties of soil have many aspects that range from semipermanent (e.g. clay content, retention of soil water) to dynamic (e.g. porosity, structure). The latter tend to change under the influence of climate and management, and tend to be soil and site specific. Generally, the methodology for soil water content and porosity is based on clear or accepted physical principles. In contrast, soil structure measurements are very method-dependent and subjective. However, though this complex situation often confounds the development of quantitative methodology, it has produced a relatively small number of reference methods that utilize a common approach to soil structure assessment.\(^4\)\(^,\)\(^5\)

2 SOIL QUALITY

Interest in evaluating the quality of soil has evolved around the various functions that soils perform in ecosystems.\(^6\) Placing a value upon soil with regard to a specific function, purpose, or use leads to the concept of soil quality. However, in contrast to water and air, where the function can be directly related to human and animal consumption, the function placed upon soil is often diverse and usually not directly linked or involved with human health. Table 1 provides a list of common soil functions.

Soil quality can only be assessed by measuring properties. However, analysis of soil properties alone cannot provide a measure of soil quality unless the properties evaluated are calibrated or related against a designated role or function of the soil. Thus, implicit in any definition of soil quality is an understanding of the stated function of the soil, or what the soil does. Soil quality can be simply defined as “the fitness of a soil for a specific use”. However, to accommodate the concepts of “sustainability” and “ecosystem”, and to stress the need to protect the environment, definitions have been expanded and developed, as indicated by the following quotation:

Soil quality is the capacity of a soil to function, within ecosystem and land-use boundaries, to sustain biological productivity, maintain environmental quality, and promote plant, animal and human health.\(^6\)

Soil quality has two parts: an intrinsic soil part which covers a soil’s inherent or natural capacity for a specific function (e.g. plant growth), and a dynamic part influenced by the soil user or how the soil is managed. This has important implications for the approach to soil analysis. Inherent soil quality properties, such as mineralogy and particle size distribution, are mainly viewed as almost static and usually show little change over time. In contrast, dynamic soil quality properties, such as organic matter, pH, and microbial parameters, are responsive to

Adapted from Gregorich and Carter. \(^6\)

soil management and manipulation, and are thus subject to change over relatively short time periods.

A useful framework to evaluate soil quality is based on the following sequence: functions, processes, attributes or properties, attribute indicators, and methodology. \(^6\)

Soil quality is evaluated on the basis of the function in question. Functions deal with “what the soil does”, or “what the soil is asked to do”. Each function can be characterized by specific soil processes that support the function which is being imposed upon the soil. Soil quality attributes can be defined as measurable soil properties that influence the capacity of the soil to perform a specific function. Generally, attributes describe a critical soil property involved with the process. In many cases the specific attribute or property may be difficult to measure directly, so an indicator can be used to serve as an indirect, practical measure of the attribute. Soil analysis is concerned with characterizing soil properties and/or indicators. It is generally acknowledged that indicators have the following characteristics: sensitivity to variations in soil management (but not over-sensitivity), relatively low sampling error, easily measurable with readily available methodology.

3 THE SOIL SAMPLE

Laboratory analysis of soil is dependent on obtaining a suitable soil sample. However, soil properties can exhibit both temporal and spatial variability, and also vary with depth. Thus, information about soil properties usually involves a sequence of steps and procedures as follows:

- description of soil sampling site;
- selection of optimum sampling time, procedure, and number of soil samples required;
- storage and preparation of soil samples;
- selection of suitable analytical method;
- calibration of the method and quality control;
- statistical analysis;
- interpretation of analytical results.

In many cases some information about site characteristics is needed as soils can vary in relation to their position within both a soil profile and the landscape. \(^1\) Even where soils appear to be uniform, the various sources of soil variation demand that an adequate sampling scheme be adopted so that valid inferences can be made about the soil population from the sample analyzed. In most cases little is known about the soil location or site, so random or probability sampling schemes need to be utilized. To accommodate different situations, various soil sampling schemes and methods have been developed for both disturbed and undisturbed soils. \(^1,7\) Some common sampling procedures are:

- simple random sampling – sample points are not influenced by other points;
- systematic or grid sampling – sample points are at regular distances from each other;
- composite sampling – sample points are grouped and the samples within each group are combined to give well mixed, but fewer, composite samples;
- spatial structure sampling – sample points are at regular distances to estimate relationships between distance and soil variation. \(^6\)

The above sampling procedures allow some measure of soil variation to be calculated for the measured variables \((x)\) in the number \((n)\) of soil samples collected. The most basic statistics are the mean \((\bar{x})\), the variance \((s^2)\),
and the standard deviation \(s\). They are calculated as shown in Equations (1) and (2).

\[
\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n} \quad (1)
\]

\[
s^2 = \frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n - 1} \quad (2)
\]

Dividing \(s\) by \(\sqrt{n}\) gives the standard error of the mean. To assess the relative degree of variability among the measured variables, the coefficient of variation (CV) can be determined. The CV can vary among soil properties from a relative low value (<10%) for soil bulk density and water-filled pore space, to a medium value (10% < CV < 50%) for soil particle size distribution, and a high value (>50%) for soil water and air permeability. The calculation for CV is shown in Equation (3).

\[
CV = \frac{s}{\bar{x}} \quad (100) \quad (3)
\]

In addition to adequate soil sampling procedures, attention must also be given to soil handling and preparation prior to analysis. These quality control considerations are a prerequisite to minimize error in all phases of soil analysis, especially those errors caused by both soil population and measurement variability. Soil handling concerns involve such things as the protocol for drying field-moist samples and the degree of grinding and screening that soil samples require prior to analysis.\(^1\text{-}\text{7,8}\) In addition, storage of soil samples before analysis requires attention to the state of the soil (e.g. dry or moist), the temperature, and the type of container used.\(^1\text{-}\text{2}\) Special precautions and conditions apply for processing soil samples for biological analyses.\(^2\) Quality control is also an important aspect of the actual laboratory analysis procedure. This includes the use of quality control procedures such as calibration of measuring instruments, use of both certified (obtained from international organizations) and internal reference samples where possible (i.e. for total concentrations of elements), and statistical quality control (i.e. routine evaluation of \(\bar{x}\) and \(s\) of the analytical values over time).

4 INSTRUMENTAL METHODS FOR SOIL CHEMICAL ANALYSIS

Soil chemical quality is important for many soil functions (Table 1). Some specific processes involved are:

- storage of organic matter
- acceptance, retention, and release of nutrients
- regulating the solubility of elements.

The primary function related to soil chemical quality for agronomic purposes is to provide nutrients for crop growth. Chemical processes and reactions also underpin other functions, such as the ability of soil to act as a filter for potential pollutants and thus reduce the risk of contamination of rivers, lakes, and aquifers. As a result of the use of pesticides and the application of sewage sludges and other wastes to land, an ability to detoxify pesticides and immobilize heavy metals is important. Chemical properties that affect these functions are mineralogy, organic matter content, cation exchange capacity (CEC), anion adsorption capacity, pH, pE, soluble salt concentration (salinity), exchangeable sodium percentage (ESP), and nutrient-supplying power.

Storage of nutrients can be viewed in terms of the quantity–intensity concept where quantity represents the total amount of nutrient held in the various supply reservoirs (in organic matter or adsorbed to clay particles) and intensity is the concentration in the soil solution at any one time. The amount and type of clay minerals in a soil determine its ability to adsorb and retain nutrient cations, and also to buffer or regulate the release of plant nutrients. Organic matter contains a store of nutrients and energy-rich compounds that, upon decomposition by microbes, provide a source of plant-available N, S, and P. In addition, the functional groups of the humic component of soil organic matter can retain cations and remove pesticides from the soil solution. The CEC of the soil reflects the contributions of both clay minerals and organic matter. The pH and pE of the soil can have a controlling influence on the solubility of nutrients, mineral dissolution, and ion adsorption. Changes in pH have major impacts on the soil as a medium for plant growth. Acid soils may contain toxic levels of soluble Al and Mn, and suffer from deficiencies of certain nutrients (e.g. Ca and P). In alkaline soils deficiencies of trace elements, especially Fe and Zn, are common due to their low solubility in the upper pH range. An excess of soluble salts, as found in saline soils, can limit the growth of plants owing to decreased osmotic potential (making it more difficult for plant roots to absorb water) and nutrient imbalances or toxicities. In some cases, trace elements can accumulate to phytotoxic concentrations, an example being the excessive boron levels sometimes found in arid areas where leaching is limited.\(^9\)

4.1 Mineralogical Analysis

Soil mineral composition is a function of the mineralogy of the parent material from which the soil is formed, and the soil weathering processes. The coarser fractions, i.e. gravel (＞2 mm), sand (50 µm–2 mm), and silt (2–50 µm), consist mainly of primary minerals such as quartz, feldspars, and micas inherited from the parent material.
X-ray diffraction (XRD) analysis is considered to be the most powerful technique available for the identification of mineral species in soil clays. Criteria for X-ray identification of the common clay minerals have been described in many texts.(7,10) Other instrumental techniques that are used in specific situations include thermal analysis (TA) (differential TA and thermogravimetric analysis), infrared (IR) spectroscopy, and magnetic methods.(1,7) Quantitative estimation of the proportions of the various minerals in soil clays usually requires the use of a combination of analytical techniques including instrumental methods and determination of the elemental composition of the material. Sand-sized mineral components can be separated by specific gravity or magnetic susceptibility and identified on the basis of their crystallographic, optical, physical, and chemical properties.

Some soil clays contain a significant amount of noncrystalline or amorphous aluminosilicate material. As such materials are transparent to X-rays, alternative techniques are needed for their determination. Noncrystalline material may be measured by boiling clay in 0.5 M NaOH for 2.5 min and determining dissolved Al and Si by atomic absorption spectroscopy (AAS). A clay/NaOH ratio (1:100) is used to avoid saturating the NaOH solution with Al or Si.

Weathering of soil may result in the accumulation of oxides of Fe and Al which frequently occur as surficial coatings on other soil constituents. Pedogenic oxides (also called “free” oxides) are important because they exhibit a strong affinity for certain anions, particularly phosphate. Free iron is determined by reducing to the soluble ferrous (Fe^{2+}) form using sodium dithionite (Na_{2}S_{2}O_{4}) as reducing agent and measuring soluble Fe by AAS.(7) This procedure also extracts Al associated with iron oxides.

### 4.2 Total Elemental Analysis

Methods for analysis of total elemental composition of soils and soil components were developed from procedures used for analysis of rocks and minerals.(7) Elemental analysis of soils requires their decomposition into soluble forms by means of acid digestion or fusion with various fluxes. The two basic procedures for bringing elements into solution are as follows.

- **fusion in Na_{2}CO_{3}** followed by dissolution of the fused sample in hydrochloric acid (HCl);
- **digestion in hydrofluoric acid (HF) alone or in HF in combination with sulfuric (H_{2}SO_{4}) and perchloric (HClO_{4}) acid**. The decomposition of silicate minerals by HF occurs by reaction of HF with Si to form gaseous SiF_{4} which is lost by volatilization if digestion is carried out in an open crucible. One method of
preventing volatile loss of SiF₄ gas is by use of a specially designed Teflon® decomposition vessel fitted with a sealed cover.\(^{(3)}\)

The acid extracts and digests can be analyzed for a range of elements (e.g. Si, Al, Ca, Mg, K, Na, Fe, Mn, Ti, and other elements) using AAS and flame emission spectroscopy (FES), as appropriate.

The recommended method for determination of total P requires conversion of mineral and organic forms of P to soluble orthophosphate by fusion in Na₂CO₃, followed by dissolution of the melt in H₂SO₄ solution. Phosphate in solution is then measured colorimetrically by the molybdate blue method.\(^{(5)}\)

Soil sulfur can exist in both inorganic (including several oxidation states) and organic forms, with the latter predominating in surface soil horizons. Methodology for determination of total S generally involves converting all of the S to a single form using a variety of wet digestion (WD) and dry combustion (DC) techniques. Alkaline oxidation in sodium hypobromite (NaOBr) converts all S to sulfate, which is subsequently reduced to sulfide (H₂S) using a mixture of hydriodic acid, hypophosphorus acid and formic acid followed by colorimetric determination of H₂S as methylene blue.\(^{(5)}\) Alternatively, the sulfate-S can be quantified by ion chromatography (IC).\(^{(1)}\)

### 4.3 Organic Matter

Analysis of soil organic matter is common in agronomic and environmental studies. Organic matter (which contains 50–58% C) is usually estimated from the concentration of soil organic C and ranges from about 0.5% to 10% in temperate region mineral soils.\(^{(3)}\) It is an important store of macro-elements that are crucial in plant nutrition (i.e. N, P, and S). N, P, and S are usually present in relatively low concentrations in soil organic matter (<5% for N, <2% for P and S). In soil science, the term “organic” is applied to elements that are associated with organic matter. For example, organic C refers to C in soil organic matter while inorganic C is found mainly in carbonates such as calcite (CaCO₃) and dolomite (CaCO₃·MgCO₃). Methods used to determine the total amounts of organic elements usually involve WD or DC techniques to liberate the element or convert it to an inorganic form.\(^{(1,3)}\) Generally, the following basic approaches can be used to determine organic C:

- WD using acid dichromate followed by back titration of the remaining dichromate using ferrous ammonium sulfate (Walkley–Black method, see Carter\(^{(1)}\));
- WD as above but with collection and determination of the evolved CO₂;
- DC in a furnace and determination of evolved CO₂ using an IR analyzer.

Modifications of these methods can include a separate treatment to measure any C present in carbonates (e.g. by neutralization of carbonate with acid and back-titration of the excess acid) which is subtracted from total C to give organic C. Alternatively, carbonates may be destroyed by treatment with dilute acid before C determination. Instrumental methods featuring automated versions of DC methods are now routinely used to determine total C and organic C in many laboratories.

Total soil N is also measured by WD (e.g. Kjeldahl method, see Carter\(^{(1)}\)) and DC (e.g. Dumas method, see Carter\(^{(1)}\)). In the Kjeldahl procedure, soil samples are digested with sulfuric acid in the presence of a catalyst and a salt to control the boiling temperature of the acid. Organic N is converted to NH₄ by the boiling H₂SO₄/salt solution. After addition of a strong alkali, NH₃ is steam-distilled into boric acid solution and titrated with standardized acid. Alternatively NH₄–N can be quantified by colorimetry using an autoanalyzer.\(^{(3)}\) The DC method utilizes high temperatures and a hot copper catalyst to convert organic N to N₂, which may be quantified using a thermal conductivity (TC) detector.\(^{(3)}\)

Part of the total soil N (up to 10% in topsoils and 30% in subsoils) resides as nonexchangeable ammonium (fixed N that cannot be replaced or extracted with a neutral K salt solution – see section 4.5), which is found primarily in the interlayer positions of certain (i.e. 2:1 type) clay minerals. This fixed N can be quantified by using KOB₃ to remove organic N followed by a HF/HCl mixture (5:1) to decompose the clay minerals containing the fixed N.\(^{(3)}\) The released NH₄ is then measured using distillation or an autoanalyzer, as described previously.

Organic P is generally determined indirectly as the difference between total P and inorganic P. Total P may be determined by Na₂CO₃ fusion as described previously while inorganic P can be measured by sequentially extracting soil with HCl and NaOH.\(^{(3)}\) Another popular method is to ignite the soil sample at 550 °C over a period of 1 to 2 h to convert organic P to inorganic P. The difference in amounts of inorganic P between an ignited sample and a separate un-ignited sample represents the amount of organic P in the soil.

As in the case of organic P, organic S is estimated as the difference between total S (determined as outlined previously) and inorganic S. Inorganic S in normally aerated soils may be assumed to be present entirely in the sulfate form, which can be extracted using a dilute phosphate solution (e.g. distilled water containing 16 mmol P L⁻¹ as KH₂PO₄ or Ca(H₂PO₄)) and measured either using IC or colorimetrically following its reduction to sulfide.\(^{(5)}\)

### 4.4 pH and pE

Soil pH exerts an important influence on growth of plants and on the activities of microbes and other soil
organisms such as earthworms. Processes of mineral dissolution generally exhibit a strong dependence on pH. In addition, the number of functional groups active in the retention of cation and anions is pH-dependent. Acid soils can be deficient in basic nutrients (e.g., Ca, P) while metals such as Al and Mn may be present in sufficiently high concentrations to be toxic to plants. Alkaline soils are often associated with deficiencies of trace elements, particularly Fe and Zn. Thus, pH provides an important indication of the soil chemical environment, with values in the 5.5 to 7.5 range being best for the growth of most plants.

Soil pH is measured using a glass, H⁺-sensing electrode paired with a reference electrode attached to a suitable voltmeter (pH meter). Soil pH is determined by inserting the electrodes into a slurry or suspension obtained by mixing a sample with distilled water or a dilute electrolyte solution (e.g., 0.01 M CaCl₂). Factors which can influence the pH value are the soil-to-solution ratio (1:1 or 1:2 soil-to-solution ratios are commonly used) and the salt or electrolyte content (pH can be a half unit lower when soil-to-solution ratios are commonly used) and the salt or electrolyte content (pH can be a half unit lower when measured in 0.01 M CaCl₂ compared with water).

Reduction–oxidation or “redox” reactions influence the solubility and speciation of elements that may exist in multiple oxidation states, especially Fe, Mn, N, and S. The redox status of a soil reflects the availability of electrons that may participate in reduction–oxidation reactions. The pE is defined as the negative logarithm of the free electron activity. Soil pE is controlled by physical conditions (water content and porosity) and biological activity. Values are usually in the –6 to 13 range. The most common method of determining electron activity in soils is to measure the potential difference between a platinum indicator electrode and a reference electrode (e.g., calomel or Ag/AgCl electrode) with a voltmeter (pH meter).

4.5 Cation Exchange Capacity

Fine mineral particles, especially clay, and organic matter carry a negative electrostatic charge on their surfaces. Such charge sites attract and hold cations which are referred to as exchangeable cations because they are easily displaced from the particle surface by other cations. In the case of clay particles, negative charge may originate through a process called isomorphous substitution whereby a cation of higher valence is replaced in the crystal structure by one of lower valence (e.g., Al³⁺ substitutes for Si⁴⁺). This type of charge is independent of pH and is often referred to as permanent negative charge. Negative-charge sites also arise from hydrolysis reactions at broken bonds at the edges of clay particles and through dissociation of acidic functional groups (e.g., carboxylic groups) in organic matter. The number of such sites increases as pH increases. The total amount of cations balancing a soil’s negative charge represents its CEC. Table 2 gives some typical CEC values of soil colloids.

In some soils, part of the permanent charge may be neutralized by positively charged polymers of hydroxy-Al or Fe oxide. Soil acidification can cause deprotonation of these Al and Fe polymers and also of hydroxy-Al and -Fe associated with organic functional groups, resulting in a positive charge and potential for anion exchange as pH declines. In the vast majority of soils, anion exchange capacity (AEC) is small compared with CEC and AEC is not a routinely measured soil characteristic.

Soil CEC is not an independent or single-value property. The value depends on pH, as discussed previously, and, in weathered soils high in Fe and Al oxides, it can also be influenced by the electrolyte concentration of the soil solution. Methods to measure CEC may involve displacement of exchangeable cations using a salt solution (e.g., 1 M ammonium acetate) followed by measurement and summation of the displaced cations, Ca²⁺, Mg²⁺, K⁺, Na⁺ (summation method). An alternative method involves replacement of native exchangeable cations by treatment with a solution containing an index cation (e.g., Na⁺, NH₄⁺, or Ba²⁺), which is then displaced and measured (displacement method). Depending on the purpose of the measurement, one may choose to determine CEC at a standard pH (commonly pH 7 or 8) or at the pH of the soil.

The following sequence is used for determination of exchangeable cations and CEC by the ammonium acetate (NH₄OAc) method at pH 7.

- A soil sample (5 g; <2 mm) is added to a centrifuge tube followed by 40 mL of 1 M NH₄OAc (adjusted to pH 7). The tube and contents are shaken, centrifuged, and the supernatant solution filtered into a 250-mL flask. A fresh aliquot of the NH₄OAc is added to the tube, followed by shaking, centrifugation, and filtration of the supernatant into the 250-mL flask.

Table 2. Typical CEC values of soil colloids

\(^{a}\) Adapted from McLaren and Cameron.\(^{(13)}\)

\(^{b}\) Value varies greatly with pH.
This cycle may be repeated to ensure complete saturation of exchange sites with NH\textsubscript{4} (3 or 4 washes with NH\textsubscript{4}OAc should be sufficient). In nonsaline and noncalcareous soils, the NH\textsubscript{4}OAc extract is retained for determination of Ca, Mg, K, and Na by AAS and FES.

- The residual NH\textsubscript{4}OAc is removed from the soil by washing several times with alcohol (ethanol or isopropanol), then the soil is washed with four 40-mL aliquots of 1 M KCl into a 250-mL flask. After bringing the KCl extract up to volume with distilled water, it is analyzed for NH\textsubscript{4} using an autoanalyzer. Exchangeable cations and CEC are usually expressed in units of mmol (+) kg\textsuperscript{-1} (millimoles of charge per kilogram of soil).

The nature of the exchangeable cation population reflects the chemical and mineralogical makeup of the soil. The exchangeable cations Ca\textsuperscript{2+}, Mg\textsuperscript{2+}, K\textsuperscript{+}, Na\textsuperscript{+} are called exchangeable bases and they normally occur in the order listed. Together Ca\textsuperscript{2+} and Mg\textsuperscript{2+} account for over 90% of exchangeable bases in most soils. Exchangeable K varies with parent material and management, particularly K fertilizer use history. Only trace amounts of Na are found in soils in humid regions, but in salt-affected arid-zone soils, Na commonly occupies 10% or more of exchange sites. The presence of this latter level of exchangeable Na can cause clay particles to disperse, leading to dis-aggregation and structural deterioration. The ESP, i.e. sodium as a percentage of the total CEC, is used to diagnose the potential for structural problems in arid and semiarid regions.

Acid conditions lead to the release of Al from aluminosilicate minerals and Al\textsuperscript{3+} can become an important exchangeable cation when soil pH is below about 5.5. Exchangeable Al\textsuperscript{3+} and H\textsuperscript{+} represent the acidic component of the CEC. In strongly acid soils, a separate measurement to determine exchangeable Al\textsuperscript{3+} and H\textsuperscript{+} is often carried out. This procedure involves use of an unbuffered salt solution (usually 1 M KCl) to extract acidic cations that are present at the pH of the salt–soil mixture (approximately the pH of the soil). The total amount of Al\textsuperscript{3+} plus H\textsuperscript{+} in the KCl extract can be determined by titration with NaOH, and Al can be measured by AAS, allowing H\textsuperscript{+} to be estimated by difference (generally the amount of H\textsuperscript{+} is small compared with Al\textsuperscript{3+}). In acid agricultural soils, exchangeable acidity is often used to assess lime requirements.

4.6 Anion Adsorption

Two mechanisms of anion adsorption in soils are generally recognized:

1. simple electrostatic attachment to positively charged sites (nitrate and chloride are adsorbed through this mechanism);
2. ligand exchange whereby certain anions (e.g. phosphate) displace –OH and –OH\textsubscript{2} ligands of Fe and Al oxides and hydroxides.

These differences in adsorption mechanisms translate to major contrasts in behavior among the principal anions found in soils. Except for those that are highly weathered and acidic, soils have negligible amounts of positive charge and do not adsorb nitrate, which is easily leached as a consequence. In contrast most soils, but especially those high in Fe and Al oxide, can adsorb substantial quantities of phosphate and its concentration in the soil solution is typically maintained at less than about 5 \( \mu \text{mol P L}^{-1} \). Sulfate is adsorbed electrostatically but it may also participate in ligand exchange to a limited extent. In general, soils with pH > 6 adsorb little sulfate. A simple index of sulfate adsorption can be obtained by shaking a 5-g soil sample with 25 mL of 0.01 M CaCl\textsubscript{2} containing 1.6 mmol SO\textsubscript{4}\textsuperscript{−}\textsubscript{2} L\textsuperscript{−1}. The amount adsorbed is calculated from the decrease in solution sulfate concentration upon contact with the soil.

Characterization of a soil’s ability to adsorb phosphate is often done by shaking samples of the soil with solutions containing a range of P concentrations and calculating the amount adsorbed as a function of the soluble P concentration. A plot of the amount adsorbed against the concentration in solution is called an isotherm (Figure 1). The isotherm may be used to estimate the soil’s adsorption capacity and its affinity for phosphate. The latter measure gives an indication of the ease with which adsorbed P is released into the soil solution. Because phosphate is adsorbed mainly by oxidic components, the content of

![Figure 1](image-url) 

**Figure 1** An example of a soil phosphate adsorption isotherm.
“free” Fe and Al can be used as an indirect gauge of the adsorption capacity.

### 4.7 Analysis of Soil Solution and Aqueous Extracts of Soil

The chemistry of the soil solution is of interest for disciplines such as plant nutrition and environmental science. The chemical composition of the solution phase of soils can vary depending on both climate and soil type (Table 3). Many chemical and biological processes are controlled by the composition of the soil solution. Methods used to isolate the soil solution include column displacement (e.g. using liquids such as saturated CaSO₄ solution or ethanol) or immiscible displacement in which a dense organic liquid such as carbon tetrachloride (specific gravity 1.6) displaces the soil solution under centrifugal force. The analytical sequence for column displacement is as follows.

- Place portions of about 30 g, moist, sieved (<6 mm) soil in a plastic or glass column (5-cm diameter; 50-cm long, with a screen or mesh attached to the bottom of the column to retain the soil) and gently pack until the soil is within a few centimeters of the column top. Place about 1 cm of acid-washed sand on top of the soil. Add the displacement liquid (e.g. saturated CaSO₄ solution containing 4 g of KSCN per liter as a tracer) to the top of the column and maintain a head (~1 cm) of solution above the sand during the displacement process. The first 2–3 mL of leachate from the column can be discarded. Subsequently, leachate may be collected in small (~5 mL) aliquots and tested for the presence of SCN⁻ by adding a drop of leachate to a solution of FeCl₃. The procedure is continued until SCN⁻ is detected (generally several hours are required to complete the procedure).

- The displaced solution is filtered to remove particulate material and analyzed for the solutes of interest using AAS, FES, or IC, as appropriate. From the analytical data, activities of different chemical species in solution may be calculated using a suitable computer program.

It is better to use single operators in analyzing soil solution samples to avoid interferences from human factors. Relatively few column displacements can be performed by a single operator in an 8 h day. The centrifuge method is more suited to routine use but, since small soil samples (10–20 g) are used, the volume collected may be insufficient for complete characterization of soil solution. Inductively coupled plasma atomic emission spectrometry (ICPAES) can be an especially useful analytical technique where solution volume is limited. ICPAES features a very high temperature (7000–8000 K) excitation source that greatly reduces molecular interferences compared with the AAS technique. In addition to its relative freedom from chemical interferences, ICPAES has a wide analytical range and low detection limits. The sensitivity of the technique allows for the complete analysis of a small quantity of soil.

Indirect estimates of soil solution composition can be obtained using soil–water extracts. Such procedures include extracts at a fixed soil/water ratio (e.g. 1 : 2) and saturated paste extracts, where the amount of water added depends on the moisture-holding capacity of the soil. The saturated paste method is a popular way of measuring soluble salts (e.g. in saline soils). The procedure is as follows.

- Place 100–200 g of air-dry soil into a plastic container and add distilled water with stirring until it is saturated. Allow the mixture to stand for several hours to permit the soil to absorb the water. Check to see that the soil is saturated (the soil paste should glisten as it reflects light and flow slightly when the container is tipped) and adjust the moisture level if necessary.

- Transfer the saturated soil paste to a Buchner funnel fitted with a retentive filter paper, apply vacuum, and collect the filtrate. The EC of the saturated paste extract provides a measure of total dissolved salts. The EC value can be used in conjunction with functions describing the relationship between crop yield and EC to evaluate the salinity hazard posed by the soil. An EC of 4 decisiemens per meter is commonly used to separate saline from nonsaline soils. From individual cation concentrations (in mmol L⁻¹) in the

paste extract, the sodium adsorption ratio (SAR), an indicator of the amount of exchangeable Na in the soil, may be calculated as shown in Equation (4).

$$\text{SAR} = \frac{\text{Na}}{(\text{Ca} + \text{Mg})^{0.5}} \quad (4)$$

Soil solution samples may be obtained in the field by vacuum extraction. The most common vacuum sampler is a porous ceramic cup. The cup is inserted to the desired soil depth, taking care to achieve good soil–sampler contact. Sample collection is accomplished by applying a suction of 50–85 kPa to the sampler using a motor-driven or hand vacuum pump. To ensure fresh samples representative of the solution in the soil pores adjacent to the ceramic cup, the initial sample is usually discarded and the second used for analysis. The time required to collect a solution sample varies with the suction applied and the hydraulic conductivity and water content of the soil. For soils near field capacity with good conductivity, enough sample for most analytical needs can often be collected in about an hour. One of the major applications of in situ solution samplers is in studies of nitrate leaching.

Other in situ or remote instruments are capable of measuring the soil solution composition, e.g., total salt concentration. In situ instruments are used extensively in agricultural research where continuous monitoring of soil solution is often needed. These instruments include porous matrix sensors, four-electrode soil EC sensors, electromagnetic-induction soil EC sensors and time-domain reflectometry (TDR).\(^{(1)}\) The first method measures the EC of soil water directly, whereas the last three methods measure the EC of bulk soil which depends on the soil water content and salt concentration.

### 4.8 Analysis of Soil Air

The composition of soil air reflects the various internal chemical and biological processes, and it is regulated by the soil moisture level and the rate of exchange between soil and the atmosphere. In addition to the major gases in the atmosphere (N\(_2\), O\(_2\), and CO\(_2\)), soil air may contain an array of other gases such as methane (CH\(_4\)), ethylene (C\(_2\)H\(_4\)), nitrous oxide (N\(_2\)O), nitric oxide (NO), ammonia (NH\(_3\)), and various sulfur gases. Generally, the major impediment to satisfactory analysis of soil air is the sampling process. In the field, various types of soil wells can be used to allow samples of the soil air to be withdrawn by syringe\(^{(1)}\) or chambers can be placed over the soil to trap emitted gases.\(^{(1)}\)

In the case of disturbed samples, incubation flasks or flow-through columns can be utilized in the laboratory. Gas chromatography (GC)\(^{(1,3,23)}\) utilizing an ultrasonic detector is the most versatile method for the separation, identification, and determination of individual gases, though the more sensitive electron capture detector may be needed to measure N\(_2\)O, a low concentration gas. Carbon dioxide and O\(_2\) are usually measured by GC using a TC detector.\(^{(1)}\) Determination of gases dissolved in the soil solution is not possible using GC, but it can be accomplished using electrochemical (e.g., platinum microelectrodes to measure diffusion of O\(_2\)) and amperometric (e.g., O\(_2\) electrode) sensors.

In the field, air wells can be used that allow the soil atmosphere to be withdrawn by vacuum after a time of equilibrium,\(^{(24)}\) or chambers can be inserted into the soil to measure the efflux of CO\(_2\) from the soil. In static closed-chamber systems, alkali solutions (e.g., NaOH, KOH) are used to passively absorb the emitted CO\(_2\), typically over a 24-h period. In dynamic closed-chamber systems, the air circulates from the chamber headspace to an IR gas analyzer and returns to the chamber (Figure 2). The chamber is coupled to a portable CO\(_2\) analyzer in a closed circuit and a small fan is used to mix the air within the closed chamber during the measurement. The portable CO\(_2\) analyzer usually contains software to calculate CO\(_2\) flux rates and has the capacity to store the data in memory which allows repeated measurements to be made. Measurements using these systems require placement of the chamber on the soil surface for a short time, typically 1–2 min; thus there is little impact of the chamber on the soil environment.

Nitrous oxide (N\(_2\)O) emissions can be measured by sequential soil air samples drawn from soil wells, or by taking a series of air samples with evacuated vacutainers at 10-min intervals over a 30-min period, and quantifying the N\(_2\)O in the laboratory with GC.

### 4.9 Analysis of Soil Nutrients

Utilization of soil as a medium to grow crops creates a need for measurement of nutrient availability. In contrast to total chemical analysis, the objective in soil test analysis is to characterize nutrient element availability to plants and assess the presence of potentially toxic elements. The soil test methodology involves selecting an appropriate chemical extraction technique which has been calibrated to crop response, for instance the level of extracted nutrient is related to crop growth and tissue nutrient concentration. This generally involves the use of mild chemical extractants that approximate the nutrient-absorbing capability of plant roots. For example, the soil test may provide a measure of nutrients in the soil solution plus those present on exchange sites, for instance the level of extracted nutrient is related to crop growth and tissue nutrient concentration. This generally involves the use of mild chemical extractants that approximate the nutrient-absorbing capability of plant roots. For example, the soil test may provide a measure of nutrients in the soil solution plus those present on exchange sites.
or pool of plant-available nutrient in the soil, rather a
dynamic equilibrium exists among solution-exchangeable
precipitated forms. Under natural ecosystems, where
plant-available nutrients can be low, the rate of internal
cycling may be more important than maintenance of a
specific nutrient level.

A wide range of soil test extractants is available,
particularly for water-soluble elements. Measurement of
exchangeable nutrients (e.g. K, NH₄) requires utilization
of another cation at sufficiently high concentration that
it will replace most of the target nutrient. Ammonium
acetate (1 M NH₄OAc) is commonly used to test for
soluble and readily exchangeable Ca, Mg, and K.
Some K may also be made available to plants through
release of the element from within the structure of
K-bearing minerals such as micas. This so-called non-
exchangeable K fraction is estimated by boiling in strong
acid such as 1 M HNO₃. For N, where plants utilize only
the mineral forms NO₃ and NH₄, both KCl and K₂SO₄
are common extractants.¹

Extraction with sodium bicarbonate (NaHCO₃) is used
to test for available phosphate.¹³ Phosphorus resides
in a variety of inorganic and organic forms in soil,
and sequential extraction schemes have been devised
to fractionate soil P into various components.²⁵ Where
detailed information is needed on a soil’s P chemistry, the
following sequence of extractants may be used: anion-
exchange resin for soluble and readily-available P, 0.5 M
NaHCO₃ for weakly-adsorbed P, NaOH for strongly
adsorbed P, dilute HCl for P in calcium phosphate
compounds, and concentrated HCl for residual P.²⁵

In the case of S, soluble sulfate can be extracted using
a weak CaCl₂ solution, while sulfate adsorbed to soil
surfaces is removed using a dilute phosphate solution.³

Many elements that are only required in small amounts
for plant growth may be toxic at higher concentrations.
Also, other elements such as heavy metals, some of which
are essential elements for plant growth, can at certain
concentrations adversely affect animal and human health.
For these elements selective extractants are required.¹³
For example, micronutrient cations (Fe, Mn, Zn, Cu)
and heavy metals such as Cd, Ni, and Pb that are nat-
urally present in the soil or added as pollutants can be
extracted using chelating agents, e.g. diethylenetriamine-
pentaacetic acid (DTPA) or ethylenediaminetetraacetic
acid (EDTA). Micronutrient anions (e.g. B, Mo, and Se)
can be removed with various extractants such as hot water
or NH₄HCO₃ + DTPA. Aluminum is a nonessential ele-
ment that may be present in the soil solution at toxic
concentrations under acid conditions. There is no spe-
cific soil test to assess Al toxicity, rather soil pH and the
exchangeable Al level may be used as indirect indicators
of a potential Al toxicity problem.

Multielement soil extractants, such as the following
Mehlich III reagent, extract several “available” plant
nutrients simultaneously:

- the extractant is composed of 0.2 M CH₃COOH,
  0.25 M NH₄NO₃, 0.015 M NH₄F, 0.013 M HNO₃,
  and 0.001 M EDTA;
- phosphate is extracted by CH₃COOH and NH₄F;
- K, Ca, and Mg are extracted by NH₄NO₃ and HNO₃;
the micronutrients Fe, Zn, Mn, and Cu are extracted by the chelating agent EDTA.

Nutrients in these extracts can be determined by colorimetric methods, AAS or ICPAES, as appropriate. The ICPAES technique offers advantages over other methods because matrix interferences are eliminated or minimized by use of high-temperature plasma, allowing multielement (e.g. K, Ca, Mg, Fe, Mn, Zn, Cu) determinations to be performed simultaneously with little or no sample preparation.\(^{(20,21)}\)

5 INSTRUMENTAL METHODS FOR SOIL BIOCHEMICAL ANALYSIS

Soil biochemical quality is important for several soil functions relating to plant growth and the regulation of soil water and energy flows (Table 1). Specific processes involved are:

- supply balance of plant nutrients
- provide suitable medium for microbes and fauna
- influence soil water storage and movement
- store and release (recycle) energy-rich organic matter.

The main attributes or soil properties used to characterize the above processes are organic matter and various fractions of organic matter (e.g. microbial biomass, macroorganic matter, light fraction), soil respiration, N mineralization, enzymes, and fauna. Figure 3 illustrates the composition of soil organic matter.

Organic matter is the prime energy source for soil organisms and as such is a central component of soil biological processes. Changes in the quantity of total soil organic matter are especially reflected by changes in the labile light fraction and macroorganic matter. The microbial biomass is both a sink and a source for nutrients and is the main agent for organic matter recycling. The soil fauna play a key role in the comminution and redistribution of organic matter in soil and thus have a profound influence on decomposition processes. Soil respiration, N mineralization, and enzymes are measures of microbial activity.

5.1 Isotopic Methods for Organic Matter

The redistribution of added substrate and residues among organic-matter fractions, particle-size or density

![Figure 3 Composition of soil organic matter, the active fraction, and the soil microbial biomass.](Reprinted from Soil Quality for Crop Protection and Ecosystem Health, Copyright 1997, 52, with permission from Elsevier Science.)
fractions, and aggregate-size fractions in soil is traceable with isotopes. Various radioisotopic techniques have been widely used since the 1960s. Recently, however, instrumentaton has become more sophisticated and readily available, allowing widespread use of stable isotopes in soil organic matter studies. The benefit of using isotopic methods is that they allow precise quantification of changes in organic matter during decomposition. Generally, $^{14}$C is used to study short-term dynamics of organic matter, and the natural abundance of $^{13}$C and $^{15}$N is used to characterize the long-term status.

For finer levels of resolution, enrichment of a substrate with labelled C or N is needed to distinguish the added organic matter from soil organic matter, because the amount of C or N added is usually small relative to the native C or N present in soil. Substrates labelled with $^{14}$C or $^{15}$N that have been used in this way range from simple compounds, such as glucose and nitrate, to complex compounds, such as cellulose and proteins, to plant leaves and roots. This approach has been used to study rapid mineralization processes (usually less than five years) and the stabilization of decomposition products over the long term. Use of a $^{13}$C- or $^{15}$N-labelled substrate offers the potential to measure precise quantitative changes as well as to monitor the changes, as seen by $^{13}$C or $^{15}$N-nuclear magnetic resonance (NMR), in chemical structure associated with the decomposition and stabilization of the added material.

Difficulties previously encountered in dating soil organic matter in samples with relatively small masses, for $^{14}$C dating and bomb $^{14}$C, has been greatly reduced by using accelerator mass spectrometry (AMS). This technique reduces the sample size necessary for $^{14}$C measurements by a factor of 2000 over conventional counting methods. This refinement has allowed the determination of high-precision dates on as little as several tenths of a gram of sample, such as that of aggregate or size fractions separated from whole soils. Radiocarbon dating of soils is based on the decay of $^{14}$C in plant material which had a $^{14}$C/$^{12}$C ratio similar to that of atmospheric $^{14}$CO$_2$ at the time of its death and incorporation into the soil. The degree to which the $^{14}$C/$^{12}$C ratio of soil organic matter differs from that of the plant material from which it is derived reflects the “mean residence time” of C in soils. Dates for whole soils and soil fractions are expressed as mean residence times, because the annual input of new plant material into soils contaminates the soil with modern C. For the purposes of assessing soil organic matter dynamics, $^{14}$C dating is done on samples that have not been enriched with bomb $^{14}$C, as described below. These soils are usually archived samples that were taken prebomb (before the 1960s) and stored in glass jars, or were obtained from under buildings. Various methods are available to calculate, report, and interpret $^{14}$C.

Detonation of thermonuclear devices in the 1950s and 1960s resulted in the enrichment of the atmosphere with $^{14}$C. This spike input of bomb $^{14}$C to the stratosphere subsequently entered the terrestrial ecosystem through plants and has then recycled through animals, microorganisms, and soil organic matter. Measurement of the rate at which this pulse of $^{14}$C moves through different fractions provides a unique opportunity to bridge the gap between the rapid turnover rates measured in labelling studies and the slow turnover rates measured in radiocarbon dating studies. Bomb $^{14}$C is determined by comparing $^{14}$C concentrations in soil sampled before 1960 (prebomb) with those in $^{14}$C-enriched modern soils. The modern soil sample should be of the same soil type and should be collected near the location of the prebomb samples.

Natural $^{13}$C and $^{15}$N abundance is another isotopic method used to characterize organic matter. Plants with a C4 photosynthetic pathway have higher $^{13}$C/$^{12}$C ratios ($\delta^{13}$C of $-12$ to $-14\%$) than C3 plants ($\delta^{13}$C $=26$ to $-28\%$). The natural abundance of $^{13}$C and $^{15}$N is expressed relative to an international standard. The $\delta$ values are calculated from the measured mass isotope ratios of the sample and standard gases using Equation (5), where $R$ is the mass 45/44 ratio of the sample or standard gas:

$$
\delta^{13}\text{C}(% \text{d}) = \frac{R \text{ sample} - R \text{ standard}}{R \text{ standard}} \times 1000 \tag{5}
$$

The use of natural $^{13}$C abundance as a tracer is based on the facts that the $^{13}$C content of soil organic matter corresponds closely to the $^{13}$C content of the plant material from which it is derived, and that there is negligible fractionation of $^{13}$C during the decomposition of plant material in soil. Thus the introduction of C4 plants to a soil previously developed under C3 vegetation (or vice versa) results in soil containing two isotopically different sources of C and provides a means of partitioning soil organic matter according to origin. This approach has been used to determine the storage of soil organic matter and turnover of plant residue C in particle-size fractions in a wide range of soils.

Nitrogen enters soils either directly through nitrogen fixation and atmospheric deposition of nitrous oxides, or indirectly through the decomposition of plant and animal residues. Atmospheric N$_2$ has a $^{15}$N abundance of 0.366% and is generally used as a standard. The $\delta^{15}$N values in living plants and residues, which vary from $-9\%$ to $+8.0\%$, increase quickly (to 10% or more) with increasing microbial transformation of the residues in litter, because of the microbial discrimination of $^{15}$N during the catabolic processes occurring in soil. Thus
successive microbial transformations of N-containing material cause a progressive increase in $^{15}$N of the soil organic matter. Changes in the $^{15}$N values allow information to be obtained on N$_2$ fixation in plants and N transformations (e.g. mineralization, immobilization, nitrification) in soil.$^{(2)}$

5.2 Analysis of Organic Matter Fractions

Organic matter C is composed of 10–25% carbohydrates, 20% amino sugars and amino acids, and 10–20% fatty acids or lipids, with the remainder as aromatic humic compounds. The latter are a complex mixture of organic compounds.$^{(27)}$ Some organic matter fractions (e.g. particulate or macroorganic matter, and light fractions) are transitory intermediates between plant litter and stable organic matter and exist in soil as fragments of recently added plant material and nonhumified material (Figure 4).

These fractions can be separated from the soil using physical methods (i.e. sieving and density separation) prior to chemical analysis.$^{(11)}$ as follows.

- **Macroorganic matter**: an air-dried <2 mm soil sample is dispersed using sodium hexametaphosphate and the soil suspension is passed through a 50 μm sieve. The sand plus organic matter on the sieve is dried and analyzed for organic C.

- **Light fraction**: an air-dried <2 mm soil sample is mixed with a heavy liquid (usually between 1.5 and 2.0 g cm$^{-3}$ at a soil/heavy liquid ratio of 1:2) such as sodium iodide or sodium metatungstate. After shaking, the solution is allowed to stand for ~48 h and the floating material is removed, washed, dried, and analyzed for organic elements. Alternatively the mixture of soil and heavy liquid may be shaken and centrifuged, and the organic matter floating on the dense solution recovered and analyzed.

![Figure 4](image-url) Light fraction organic matter as a transitory intermediate between plant litter and stable organic matter.$^{(14)}$ (Reprinted with permission from M.R. Carter, B.A. Stewart (eds.), *Structure and Organic Matter Storage in Agricultural Soils*, Copyright Lewis Publishers an Imprint of CRC Press, Boca Raton, FL, 1996.)

Soil carbohydrates are generally extracted by acid hydrolysis (e.g. concentrated H$_2$SO$_4$) to release saccharide monomers and the hydrolysate is analyzed for individual monosaccharides by liquid chromatography (LC) and GC, or for total saccharides by colorimetric methods.$^{(1,8)}$ Owing to the great variability in soil carbohydrate complexity and resistance to hydrolysis (e.g. cellulose), and the need to extract carbohydrates that are implicated in soil aggregation processes, dilute acid (e.g. 0.5 M H$_2$SO$_4$) is often used as the extractant. Nitrogen compounds (e.g. amino sugars or acids) are also extracted by acid hydrolysis (e.g. using concentrated HCl) and the neutralized hydrolysate is analyzed for the organic form of N using the Kjeldahl steam distillation procedure or by colorimetric methods.$^{(1,3)}$ Soil lipids are extracted using organic solvents (e.g. chloroform) which separate the lipids from their association with carbohydrates and proteins, and the extract is analyzed for lipid composition by chromatographic fractionation.$^{(3)}$ In many cases, an acid pretreatment is needed to separate lipids bound by clay minerals or iron and aluminum salts.

There are several spectroscopic techniques for chemical characterization of soil organic matter: NMR spectroscopy is a nondestructive technique to study organic C because the organic matter is not extracted from the soil for analysis. The results therefore provide a chemical view of the organic material as it exists in soil. A range of NMR techniques has been used to study organic materials in soils on different nuclei ($^{13}$C, $^{15}$N, and $^{31}$P) in whole soil or soil fractions in solutions and solids. Cross-polarization/magic angle spinning (CP/MAS) methods are often used to enhance signal intensity and obtain well-resolved spectra. Solid-state $^{13}$C-NMR has been used to characterize organic C in different chemical structures that are differentiated on the basis of chemical shift (i.e. units of parts per million of applied magnetic field). Because soil organic matter comprises a heterogeneous mixture of different types of organic C, the spectra for most mineral soils with <50 g C kg$^{-1}$ soil are usually divided into four regions of chemical shift: alkyl C (0–45 ppm), O-alkyl (45–110 ppm), aromatic C (110–165 ppm) and carbonyl C (165–220 ppm).$^{(28)}$ These C compounds denote the most dominant form of organic C present within each region. The integral of the signal intensity across a chemical region is usually expressed as a proportion of the total integrated area of the spectrum and the NMR results should not be considered quantitative unless detailed NMR experiments are performed.$^{(28)}$

Other spectroscopic techniques that have been used to characterize the chemistry of soil organic matter involve mass spectrometry. In pyrolysis/mass spectrometry (py/MS) the sample is pyrolyzed (i.e. heated rapidly
at high temperature to release organic material) directly in the vacuum of a mass spectrometer.\(^{[27]}\) The components can be identified using several ionization methods, including field, chemical, and laser ionization as well as fast atom bombardment. The spectra result in a pattern of pyrolysis products with signals at specific values which correspond to particular types of organic molecules. A fundamental assumption underlying these techniques is that little fragmentation occurs during the sample pyrolysis.

The development of techniques to separate humic compounds was driven partly by the need to isolate soil organic matter in forms that are both high in C and relatively soluble. The traditional approach to analyze soil humic compounds is by extraction with alkali (NaOH) followed by acidification (HCl) of the extract to obtain the humic, fulvic, and humin fractions. The three fractions can be analyzed by various chemical methods to obtain their overall chemical composition. However, since humic compounds are not discrete substances, but rather are heterogeneous and complex in nature and cannot be defined in specific chemical terms, information on their composition alone is of limited value. Most interest is directed to characterizing the major functional groups (i.e. carboxyl, alcohol, phenolic hydroxyl, and carbonyl) that provide information on the structural composition of humic compounds and how they function in soil and water ecosystems. It is imperative that a standard methodology be used in separating humic compounds because small changes in the type and concentration of the solute during the extraction significantly alter the partition of C into these compounds. Several instrumental methods are available to study the structure of humic substances, such as \(^{13}\)C NMR spectroscopy, Fourier transform infrared (FTIR) spectroscopy, electron spin resonance (ESR) spectroscopy, py/MS, and supercritical gas extraction (SGE).\(^{[27]}\)

### 5.3 Microbial Biomass

The magnitude of the soil microbial biomass is of interest, especially for ecological studies concerned with the biomass as a sink and source of nutrients. Light microscopic methods have been developed to estimate bacteria and fungal biomass by using cell length and width dimensions, and a dry weight/cellular volume conversion factor.\(^{[2]}\) However, such methodology is time-consuming. Several techniques have utilized the change in the soil respiration rate, as a result of exposing the soil to a fumigant or by adding a C substrate (e.g. glucose), to estimate microbial biomass.\(^{[2,3]}\) In the former approach, a soil sample is fumigated under specific conditions with a fumigant (e.g. CHCl\(_3\) vapor) to kill the living microbes. The resulting increased decomposition, in comparison to an unfumigated soil, as measured by the release of CO\(_2\) over a specific period of incubation (i.e. 10 days) is directly proportional to the size or amount of C in the biomass. The release or flush of CO\(_2\) after fumigation is the result of germinating microbial spores utilizing the C substrate provided by microbial cells killed by the fumigant. Fumigation techniques are suitable for estimating the C, N, P, and S content of the soil microbial biomass.\(^{[1–3]}\) Replacing this incubation step by directly extracting the soil immediately after fumigation provides a relatively rapid chemical method to estimate the size of the biomass. The following list gives the analytical sequence for determining microbial biomass C using the CHCl\(_3\) fumigation–extraction method.

- **Soil sampling and preparation:** soil cores are obtained according to an acceptable sampling scheme to provide a measure of soil variability. The field-moist samples can be stored for up to a week at 4°C or stored overnight at 15°C. Soil is passed through a 4–6-mm sieve prior to analysis to homogenize the sample. Three soil subsamples (e.g. 15–50 g) are placed in glass beakers one of which is immediately extracted with K\(_2\)SO\(_4\) (see final step).

- **Fumigation treatment:** under a fumehood, the two remaining soil subsamples are placed in a desiccator, along with a beaker containing purified or heptachlor epoxide stabilized (i.e. ethanol-free) CHCl\(_3\) (50 mL) and boiling chips. A vacuum is applied until the CHCl\(_3\) boils vigorously, then the sealed desiccator is maintained under vacuum in the dark at 25°C for 24 h.

- **Extraction of microbial biomass C:** the vacuum in the desiccator is carefully released, the CHCl\(_3\) removed (and disposed of as a hazardous waste), the beakers containing the soil samples removed, and 0.5 M K\(_2\)SO\(_4\) added to each beaker (to give 1:2 to 1:5 ratios of soil to extract). After shaking for 1 h, the soil suspension is filtered and the filtrate analyzed for organic C on a total organic C analyzer.

After adjusting the soil weight to an oven-dry basis (using Equation 6) and correcting for the total volume of the solution in the extracted soil (Ext. mL = soil wet wt. – soil dry wt. + mL of K\(_2\)SO\(_4\) added), the total weight of extractable C in fumigated (CF) (i.e. average for the two samples) and in unfumigated (CUF) soil, and the microbial biomass C are calculated using Equations (7) and (8).

\[
\% \text{H}_2\text{O (mass)} = \frac{\text{(mass of wet soil, g)}}{\text{(mass of dry soil, g)}} \times 100
\]

\[\text{Equation 6}\]

\[
\text{Equation 7}
\]

\[
\text{Equation 8}
\]
CF or CUF (µg g⁻¹ soil) = extractable C (µg mL⁻¹)

\[
\text{mg CO}_2\text{C g}^{-1}\text{soil for the incubation time.}
\]

\[
\text{mg CO}_2\text{C g}^{-1}\text{soil} = \frac{\text{mg CO}_2}{W}
\]

where 0.25 is the efficiency of extraction (k_{ex}) of microbial biomass C based on in situ calibration techniques. \(^{(1)}\)

### 5.4 Analyzing Microbial Processes

Microbial activity can influence the mineralization and transformation of many soil elements, such as C and N, and influence the composition of the soil air (e.g. CO₂, N₂O, NO, O₂). Most methods devised to characterize microbial processes in soil are concerned with estimating C and N transformations. However, methods are also available to assess other microbiologically mediated transformations such as the oxidation and reduction of S, Fe, and Mn. \(^{(2)}\) Carbon mineralization involves the biological oxidation of organic C, where CO₂ is released to the soil atmosphere from metabolizing soil microbes and fauna. Soil respiration is defined as the sum of the soil’s metabolic activities that produce CO₂. \(^{(2)}\) In order for the method to give an accurate measure of the activities in soil it is important that the conditions of the incubation (i.e. temperature and soil moisture) be carefully controlled under standardized conditions. Laboratory methods to measure soil respiration generally involve use of incubation chambers, where CO₂ evolved from a soil sample is trapped in an alkali solution as carbonate, which can then be measured by titrimetric, gravimetric, or conductimetric analysis. For analysis of CO₂ in gaseous samples, GC or IR gas analysis can be used. In the static method, titration of alkali solutions exposed to incubated soils determines the quantity of NaOH not reacted with CO₂. \(^{(1)}\) The dissolved CO₂ is precipitated as BaCO₃ and phenolphthalein is used as the end-point indicator. The steps in the static method are as follows.

- A soil sample (W, g dry soil) in a beaker is placed in an incubation jar, along with a beaker containing a 1 M alkali solution (e.g. KOH, NaOH), and the jar is sealed. A water blank and a NaOH blank are also incubated separately.
- After a period of time the NaOH beaker is removed from the jar, and an excess of 1.5 M BaCl₂ with a few drops of 1% phenolphthalein indicator solution are added to the beaker. The solution is then titrated with 1 M HCl (S). Both the water and NaOH blank (B) are also titrated. Equation (9) is used to calculate...
Microbial processes in soil are mediated by enzymes that serve as biological catalysts. They control organic matter decomposition and their activities reflect conditions in the ambient environment (i.e. soil moisture and other environmental parameters). Generally, laboratory methods used to measure enzyme activities in soil involve the incubation of a soil sample with a specific substrate, under standard conditions, followed by determination of the rate at which the substrate is converted to a measurable product.\(^2,3\)

### 6 INSTRUMENTAL METHODS FOR SOIL PHYSICAL ANALYSIS

Soil physical quality is important for many soil functions such as the medium for plant growth, and regulation of water and air\(^29\) (Table 1). Specific processes involved are:

- provision of a suitable medium for root growth and development
- acceptance, retention, and release of water
- permeability for air and water movement.

The main attributes or soil properties used to characterize the above processes are clay and organic matter content, hydraulic conductivity, pore size distribution, macropore space and organization, oxygen diffusion rate (ODR), bulk density, soil strength, and aggregate stability.\(^29\)

Many of these properties reflect the ability of soil to store and transmit water, solutes, and gases. Inherent soil properties, such as clay content, influence the magnitude of the soil water holding capacity. This is also augmented by the organic matter content. Dynamic soil properties, such as soil density and porosity, control the soil storage capacity for water and air. Pore size distribution is considered to be a good indicator of the soil structural condition and has proven useful for predicting water infiltration rates, water availability to plants, soil water storage capacity, and soil aeration status.\(^20\)

Macroporosity, air permeability, and/or ODR provide a measure of soil macropore continuity and organization. Soil strength and aggregate stability reflect a soil’s ability to resist compaction and other stresses that can lead to loss of structure.\(^29\)

Instrumentation, based on analytical chemical methods, is available for the analysis of soil water, porosity and aeration, and macrostructure and bulk density.

#### 6.1 Soil Water Analysis

The water content of soil is one of the most commonly measured parameters in soil analysis.\(^30\) A simple approach to estimate total water content is to determine the loss of mass after oven-drying a soil sample at 105 °C to a constant mass. The analysis can be expressed as the ratio of the mass (or the volume, i.e. assuming the bulk density of H\(_2\)O to be equal to one) of water and dry soil as shown in Equations (6) and (10).

\[
%\text{H}_2\text{O} \text{(volume)} = \frac{\%\text{H}_2\text{O} \text{(mass)}}{\text{soil bulk density}} 
\]

In many cases the ratio of the volume of water and dry soil is used, especially if the soil is a swelling soil. Soil water content can range from near zero to a variable level associated with the volume of the soil pore space. In addition to oven-drying procedures to calculate the mass of soil water, various instrumental techniques are available.\(^1,7\) TDR is based on the electrical properties of the water molecule, specifically the dielectric constant of water which is much higher than that of soil solids or air.\(^31\)

Thus, the dielectric constant of soil is related to the water content. The TDR method is useful for both laboratory and field use. For mainly field studies, or with large bulk soil samples, the neutron thermalization (NT) method and the \(\gamma\)-ray attenuation (GRA) method can be used. NT uses high-energy fast-moving neutrons, which are scattered and slowed to the level of thermal energy by collisions with nuclei of similar mass and size, such as the H nuclei. As most H in soil is in water, the intensity of thermal neutrons provides a measure of soil water content. GRA uses \(\gamma\)-rays which are passed through the soil and absorbed by soil particles and water. Thus, under conditions where soil solids are maintained at constant density the degree of GRA or reduction in intensity is related to soil water content.

Water in soil is held in a certain physiochemical state that can be characterized in terms of free energy per unit mass or potential.\(^1,7\) The potential (\(\Phi\)) is related to the sum of the various forces in soil that hold on to water (e.g. matric, osmotic, gravitational). Matric potential arises from the attraction of the soil solids for water, while the osmotic potential relates to the influence of dissolved solutes on water activity. For methodology purposes, water potential relates to the amount of work expressed in terms of pressure (i.e. megapascals) required to remove water from the soil system. Matric potential can be measured using resistance blocks, tensiometers, and water desorption curves. Resistance blocks contain electrodes embedded in a matrix of porous material such as gypsum, fiberglass, or nylon. After equilibration in soil, the EC of the block can be related to the soil matric potential. Resistance blocks are generally better suited to dry soil conditions and have the disadvantage of a slow response time to changes in soil water. Tensiometers are composed of a porous ceramic cup attached to a tube with an airtight cap and a side arm containing a device
to measure the pressure of the water in the tube. The porous cup allows water to move freely between the soil and tube, and thus the hydrostatic pressure within the tube can be related to the soil matric potential. Use of tensiometers is generally restricted to wet soil conditions.

The thermal properties of soil are related to soil water content. On this basis, the TC of soil has been used as an indirect measurement for soil matric potential. TC sensors have been developed that use the thermal properties of a standard porous medium (e.g. ceramic porous media). The sensor, placed in a soil, will at equilibrium give TC measurements that are related to the soil matric potential.

6.2 Characterizing Porosity and Aeration

Soil porosity parameters reflect the character of soil as a three-phase system of solids, liquids, and gases. Porosity measurements are useful indicators of the soil physical condition, especially the distribution of the total pore space into different categories of relatively large diameter pores that influence the movement of water and air.

Total soil porosity (St) is a measure of the volume percentage pore space and can be estimated from soil dry bulk density (Db) and soil particle density (Dp) as shown in Equation (11).

\[
St = 1 - \left( \frac{Db}{Dp} \right)
\]

The Db parameter can be considered as the ratio of the mass of oven-dried soil solids to the bulk volume of the solids plus pore space, while Dp is often assumed to approximate the Dp of quartz (i.e. 2.65 Mg m\(^{-3}\)). Greater accuracy for Dp can be obtained by the use of a pycnometer. In moist soils there is usually a need to further characterize the total pore space into air-filled porosity and water-filled porosity, and to obtain a measure of pore size distribution. The air-filled porosity (Fa) is the fraction of the soil bulk volume occupied by air at a certain moisture content, or preferably the soil matric potential.

The water-filled porosity parameter (Fw), often called "relative saturation", expresses the volume of water in soil relative to St. It can be simply calculated from St and Fa as follows: Fw = St – Fa. Generally, a Fw over 65–70% indicates anaerobic conditions.

These parameters of soil porosity are usually “static” as they provide little information about the movement of air or water in the soil. In many cases, both the size and continuity of pores is of interest. The latter characteristic is the main influence on air and water movement in soil. Micromorphological methods can be used to directly determine the shape and continuity of pores > 100 µm. Soil cores can be sectioned and visible soil pores segregated or classified (e.g. macrostructure of pores > 200 µm) on the basis of size and shape to provide a semiquantitative analysis. Noninvasive instrumental methods, such as computed tomography (CT), have been developed to obtain images of the distribution of pore space. Several types of CT techniques are available based on X- or γ-ray transmission, NMR, and ultrasound.

A sensitive method of assessing pore continuity involves use of a gas at low pressures. In contrast, use of water to assess pore continuity may significantly change the soil pore structure over time. Air permeability can be measured in the laboratory, using soil cores, by the constant pressure gradient method. In this method an air flux, obtained from a pressurized air bottle and regulated by a pressure gauge, is passed through a soil core of a certain length (L, cm) and cross-sectional area (A, cm\(^2\)) at a constant low pressure (e.g. 2.5 cm water) as measured with a water manometer, and the volume of air (V, cm\(^3\) s\(^{-1}\)) passing through the core is measured with a flow meter. A low air pressure is used to prevent turbulent flow in the soil core which may change the pore size distribution as the air flows through the soil. The air permeability coefficient (K, cm\(^2\)), termed the intrinsic permeability to air, is calculated as shown in Equation (12).

\[
K = (V) \left( \frac{L}{A} \right) \left( 7.4 \times 10^{-8} \right)
\]

The constant 7.4 \times 10^{-8} represents the air viscosity at 22°C and a constant air pressure of 2.5 cm water (0.25 kPa).

A useful method of assessing soil aeration involves the use of a platinum microelectrode to measure the ODR through the liquid phase of the soil. The microelectrode (cathode) is connected by an electrical circuit to a reference Ag–AgCl electrode (anode) which has a KCl-saturated agar gel salt bridge. The procedure is given in the following list.

- The platinum microelectrode (A, surface area, m\(^2\)) is inserted into the soil or soil core along with the reference electrode which is connected to the soil via the salt bridge.
- A voltage is then applied (usually −0.65 V or less) between the electrodes, and the steady-state current (i, µA) is measured. The latter is proportional to the flux of O\(_2\) at the surface of the platinum microelectrode.
- The ODR (µg m\(^{-2}\) s\(^{-1}\)) is then calculated as shown in Equation (13).

\[
ODR = \left( \frac{i}{A} \right) \left( 8.3 \times 10^{-5} \right)
\]
The constant $8.3 \times 10^{-5}$ equals the molecular weight of $O_2$ (32) divided by the product of the number of electrons (4) required to reduce one molecule of $O_2$ and the Faraday constant (96,500 coulombs per mole of $O_2$). The micro-electrodes should be periodically cleaned to remove soil colloidal material or salts that could influence the potential and subsequently the output current. The method is conducive to sequential measurement by multiple micro-electrodes, which can be retained in the soil at different depths. The platinum electrode, as a combined unit with the Ag—AgCl anode and KCl electrolyte, can also be used as an electrode to measure directly $O_2$ concentration in both the gaseous and solution phases of the soil.

### 6.3 Macrostructure and Density

Soil structure has been variously defined but in the broadest sense can be described as the spatial arrangement of both soil particles and voids. In this regard, soil structure has significant effects on air–water relationships in soil.\(^6\,6\,3\,2\) The structure of soil secondary particles can be placed into three broad categories as follows:

- single grained (sometimes referred to as ‘structure-less’), completely unattached particles as in sands;
- massive, tightly packed particles (e.g. compacted clay soil);
- aggregated, where primary particles associate to form secondary particles or aggregates.

Soil aggregates formed under natural conditions (called peds), without the aid of soil tillage or other forms of soil disturbance, are characterized by their shape, arrangement and size. However, the shape and size of aggregates in cultivated soils can be greatly modified by agricultural practices. Thus, the emphasis is placed not only on the size and arrangement of aggregates, but also on the stability of the aggregate arrangement.

The formation of soil aggregates is dependent upon both abiogenic and biotic factors, the former being mainly related to soil clay content and the capacity for natural (e.g. alternating shrink–swell, freeze–thaw, wet–dry) structure-forming processes. The aggregation process is not totally random but occurs with some degree of order, in that for many soil types where biotic factors are the main aggregating agents small soil particles are apparently stabilized in large particles.\(^4\,3\,4\) Although soil specific, this ordering or arrangement of particles and aggregates can be viewed conceptually as a hierarchy consisting of three main orders:\(^4\)

- clay microstructures (<2 $\mu$m diameter)
- microaggregates (2–250 $\mu$m)
- macroaggregates (>250 $\mu$m).

In soils (e.g. Oxisols) where inorganic compounds (Fe and Al oxides) are the main aggregating agents this hierarchical order may not be evident. In clay microstructures, clay–organic matter complexes are stabilized by humic acids and inorganic ions (e.g. Ca). Microaggregates are stabilized directly by microbial materials such as polysaccharides, hyphal fragments, and bacterial cells or colonies.\(^4\) In comparison, the formation of macroaggregates and their temporary stabilization is the result of a combination of mechanisms related to plant roots and the activity of soil fungi and fauna. Figure 5 provides a schematic diagram of the structure of micro- and macroaggregates.

Generally, the study of soil structure is usually not related to soil structure itself (i.e. the spatial heterogeneity of the different components or properties of soil) but rather to the “functionality” of soil structure, or how an aspect of structure affects specific soil processes. A useful approach to describe soil structure in agricultural soils, which accommodates both aggregates and pores, is to characterize structure on the following basis:\(^3\,4\)

![Figure 5 Diagram of the structure and components of soil micro- and macro-aggregates.](Reprinted with permission from M.R. Carter, B.A. Stewart (eds.), Structure and Organic Matter Storage in Agricultural Soils. Copyright Lewis Publishers an Imprint of CRC Press, Boca Raton, FL, 1996.)
• structural form – arrangement and size of the pore space;
• structural stability – ability to retain the distribution and size of its aggregates after exposure to various stresses (e.g. external forces of impact, shear, abrasion, and slaking);
• structural resiliency – ability of a soil to recover its pore space arrangement after the removal of a specific stress (e.g. compaction).

Soil Sampling for the Characterization of Hazardous Waste Sites

Brian A. Schumacher, J. Jeffrey van Ee, and Evan J. Englund
United States Environmental Protection Agency, Las Vegas, USA

1 Introduction

The planning for and collecting of samples at hazardous waste sites is nearly always the first step in any program that involves the analysis of real-world soil samples. Knowledge of numerous different, yet related, topics, such as data quality objectives (DQO), sampling network design, quality assurance (QA)/quality control (QC), documentation, site characterization, sample collection, and sample handling and preparation, is essential to ensure the success of any program in obtaining accurate (non-biased), precise, and representative soil samples. It is often quoted that during sample collection, 80% or more, for stable contaminants (e.g. heavy metals, polychlorinated biphenyls, polyaromatic hydrocarbons), ranging up to 99.9%, for less stable contaminants (e.g. volatile organic compounds (VOCs)), of the total measurement error associated with a sample occurs. Hence the goal of the program planner is to develop the most efficient sampling design that collects the desired samples while minimizing sample errors. If all of the aforementioned topics are not taken into account during the sample planning and collecting phases of the program, then no matter how good the analytical data may be, the data may lead to incorrect decisions with respect to the extent, distribution, and need for remediation of contaminants at a site.

1 INTRODUCTION

The sampling of soil, or any heterogeneous medium, requires an understanding of the spatial and temporal scales of interest to the decision makers. Depending on how the medium is sampled and analyzed and the data are processed, almost any “valid” contaminant concentration can be obtained. In the absence of other data, data from the sampling and analysis of soil (or hazardous waste) is frequently assumed to represent the actual contaminant concentration in the vicinity of the sampling point when emphasis is placed on characterizing the distribution of a contaminant in the soil. When additional data are obtained in the vicinity of that sampling point, differences in contaminant concentrations almost always occur. The dilemma, then, is to try to determine the true concentration of the contaminant within a given area or volume of soil using the most efficient sampling design and minimizing the errors that occur during sample collection.

This article will provide a basic understanding of the processes and factors involved in the sampling of soils at a hazardous waste site. These processes and factors can be divided into several general categories, which include sample planning, documentation, QA, QC, sampling network design, site characterization, sample collection, and sample handling and preparation concerns. Basic guidance on dealing with factors influencing accuracy, precision, representativeness, and comparability of data and how to develop concise statements of the sampling effort objectives will be emphasized. Interpretation of the collected data will be discussed as a means for not only answering the basic objectives of the sampling effort, but also determining whether the quality of the data is sufficient to meet the needs of the user. Information on how to answer some of the most frequently asked questions, such as, “How many samples are needed and where
should they be taken?”, will be provided. Regrettably, no simple answers exist. Once the planning phase is completed and the soil sampler goes to the field, discussion of site features that influence the distribution and ultimate management of the contaminants at the site and how to correctly collect the soil sample will be presented. Unfortunately, no checklists are capable of addressing all of the important issues and factors that influence the sampling and analysis of soils and heterogeneous models. Site characterization and soil sampling are multimedia, multidimensional, multidisciplinary efforts that require vigorous communications between all of the principal parties involved. A genuine grasp of the basic concepts and critical definitions is extremely important to perform efficient and effective soil sampling for characterizing hazardous waste sites. The American Society for Testing and Materials (ASTM) is currently preparing a practical manual describing all of the different aspects of soil sampling at hazardous waste sites that are discussed in this article. The ASTM manual provides “real-world” examples (including site data) and covers all aspects of soil sampling from planning through implementation and assessment making the manual a valuable companion document for this article.

2 SAMPLING PLANNING

Typically, at the beginning of a site investigation, historical information is sought to allow hypotheses and conceptual models of the site to be developed. All potential pathways of contaminant movement and exposure routes to living organisms should be identified and addressed. For example, if the contamination is in the soil, one pathway of concern may be the migration of the contaminant to the groundwater. The project planners should use the limited historical information about the site to determine what additional data are needed and where to collect it to address the critical questions of how much risk the site poses to humans and the environment.

Data are collected from a variety of sources and from a variety of locations to develop a “conceptual model” of the site. There may be no one complete conceptual model that exists for a given site and other models may need to be developed as the site investigation progresses and new information becomes available. A variety of mathematical models, and sometimes physical models, may be employed to estimate data between collected data points and to predict data at other times, at critical receptors, and in other media.

Far too often, efficient collection of samples and data is difficult because critical definitions and well-defined problem statements are often lacking at the beginning of an investigation, even though the conceptual models may have been well defined. Usually, the controlling factors regarding the amount, quality, and type of data collected are time and money and not whether the results will adequately represent the site, fill the data gaps, or allow for a defensible decision to be made. The traditional thinking is that the more data that can be collected, the better the final conceptual model and decision-making process become.

Data that are collected in a site investigation are often viewed in a spatial context. The increasing popularity of computer-based geographical information systems (GIS) permits the rapid display of both two- (2-D) and three-dimensional (3-D) data. While data from a site investigation are frequently analyzed using classical statistics, geostatistics is increasingly being used. None of these tools, however, can properly be used to answer critical questions about a site unless the critical questions have been properly highlighted and defined. Frequently, the generally accepted critical question that drives an investigation is whether an action level for one, or a variety of contaminants, is being exceeded. This question, by itself, is meaningless unless the “support” or spatial volume that accompanies the action level is prescribed. Sampling heterogeneous materials, such as soil, can lead to a wide range of valid contaminant concentrations from which comparisons with an action level may be made depending upon the volumes of material that are being represented. For example, the concentration of a contaminant in a 5-g sample may exceed the action level whereas the concentration of contaminant in a soil core sample from which the 5-g subsample was obtained may not exceed the action level.

2.1 Terminology

A number of spatial units need to be considered and defined early in the investigation of a hazardous waste site in order to permit the efficient collection of data and the answering of critical questions (Figure 1). All of these units are used in the development of the conceptual model for a site.

The first unit to consider is the “distribution unit”. The distribution unit is the volume of soil that has been contaminated. A large site may consist of a number of distribution units (i.e. contaminated areas). Different processes may have been involved in the distribution unit for distributing the contaminant. The contaminant may have been “uniformly” distributed as one might expect in a settling pond. Conversely, a contaminant may be distributed irregularly if leaking drums were stored in the contaminated area. Knowing in advance how the contaminant may have been distributed at a site should influence the decision-making process for determining how and where samples must be collected to answer
critical questions about the site. The sampling procedures and number of samples needed to characterize an area where leaking drums were stored can be expected to be different than for the bottom of a settling pond.

The second unit to consider before an investigation progresses significantly is the “exposure unit”. The exposure unit is the volume of material, in this case soil, for which an action level or threshold concentration applies. Unfortunately, action levels are typically listed without the accompanying exposure unit. Action levels may be listed for humans for residential or industrial exposures, but usually the spatial area for which a person may be exposed to the action level (for some period of time and experience little risk) is seldomly defined precisely. Exposure units need to be defined as precisely as possible before extensive data collection begins if the exposure unit is going to serve as the foundation for the decision-making process. It may be necessary to spend some time to examine the basis and data for the action level to determine the type of exposure, underlying assumptions, and area for which actual exposure and risk of contact with the contaminant is of concern. For example, “Does the ‘residential exposure unit’ assume 0.6 ha (1/4 acre) lots for which an individual may be exposed over a lifetime, on average, to unacceptable risks from the contaminant?”. Alternatively, “are hot spots within the exposure unit of greater concern because the exposure and dose to children are expected to be higher?”. These are potential questions that must be considered when defining the exposure unit.

The establishment of the exposure unit, together with the action level for a contaminant, is important in the development of the conceptual model and the associated decision-making process in a site investigation.

The third unit, the “remediation unit” is related to the “exposure unit” through the decision-making process and conceptual models in a site investigation. If the measured and estimated contamination within an exposure unit exceeds an action level, then presumably remediation needs to occur. A remediation unit may then be defined as the smallest practical volume of soil at which a cost-effective remediation can occur. The issue of the smallest practical volume is important since not only is it defined by the contaminant concentrations present but it is also operationally defined by the sampling and remediation equipment to be used during site restoration. For example, if sampling were done with tablespoons, and estimates of exposure units show that remediation is required, backhoes, rather than tablespoons, would more likely be used to remediate the area. Although samples were collected with a small support and decisions were based on those data, decisions would likely be made and based on a larger support. If only a small fraction of the exposure unit were contaminated (i.e. a hot spot), would it be necessary to remediate the entire volume of the exposure unit, or can smaller areas be remediated? It may be possible to make decisions that are less costly on the basis of remediation units, e.g. backhoe volumes, rather than entire exposure units.
Addressing the volume of the “remediation unit” at the beginning stages of a site investigation allows for development of decision rules (to be discussed) that can guide the decision-making process and the subsequent selection of sampling procedures, analytical methods, and concentration estimation methods.

The problem of “hot spot” identification and the required, optimal sampling network becomes easier to address if the remediation units have been defined at an early stage. If “hot spots” were identified through the use of tablespoon samples at a particular grid spacing, it would not be practical to define precisely the boundaries of the hot spot at a relatively small spatial scale if a backhoe were used to remove contaminated areas. High-resolution sampling for hot spots may not be cost-effective if the area to be effectively and economically remediated is on a larger scale. Definition of the “remediation unit” prior to the collection of a significant number of samples from the field permits the costs in obtaining data at various spatial densities (to address a decision rule) to be balanced against the costs in remediating the area with no further information or data being required.

2.2 Data Quality Objectives

All three previously defined units, the distribution, exposure, and remediation units, may be used in the DQO process to achieve an optimization of the site characterization process. The DQO process fosters communications and the development of critical decision rules for the study of soils and hazardous waste sites (Figure 2). A stepwise, iterative process, involving major participants in the decision-making process for a site, is used to focus attention and resources on the critical questions or hypotheses that need to be tested. A variety of questions may be answered in an investigation but there are usually just a few contaminants and questions that drive the decision-making process for a site investigation. An example of a decision rule would be, “If the mean concentration of arsenic exceeds the action level within the exposure unit by 10%, then the unit should be remediated by progressively removing those remediation units that contribute to the exceedance”.

The DQO process has been used in the past to establish objectives for precision, accuracy, representativeness, completeness, and comparability for the reported data. The major focus of QA/QC efforts has been on the analytical phases of the sample collection and measurement process. Current DQO guidance from the United States Environmental Protection Agency (USEPA) attempts to focus more efforts towards examining the sensitivity of the decision-making process to all key inputs, rather than just those related to sample analysis. In other words, “What are the effects on the basic decision-making process (i.e. the decision rule) from imprecise, inaccurate, nonrepresentative, incomplete, and incomparable data from a variety of sources?”. This change in emphasis in the DQO process recognizes that there are numerous, and often significant, sources of variability outside the analytical process. There is variability in the process that is used to estimate contaminant concentrations and other physical parameters between measured points. There are errors introduced in the sample collection, subsampling, sample preparation, and sample transportation steps. All of these steps can introduce errors that are significantly greater than those encountered in the analytical process. A well-executed DQO process considers, in parallel, the tolerance for error in the basic decision-making process as well as the tolerance for error in the sample collection and measurement processes.

Further information on the DQO process may be found in the Guidance for the DQO Process(3) and The DQO Process for Superfund: Interim Final Guidance(4) documents. A related document, Guidance for Data Quality Assessment(5) describes statistical methods for evaluating data to determine whether the DQOs have been met.

3 QUALITY ASSURANCE/QUALITY CONTROL

The overall goal of the QA/QC program in any investigation is to assess and ensure that the variability in the data is attributable, as much as possible, to the media and environment that is being measured and not to the measurement (including sampling) process. A properly designed and implemented QA/QC program can
achieve that goal. In the field, QA/QC samples may be placed in the sample collection and preparation processing stream at several different locations. Depending upon their placement, a variety of different errors can be assessed. However, the determination of the number, type, and placement of QA/QC samples within the sample stream is as problematic for a site investigation as the determination of the number, type, and location of routine samples that must be collected. All too often the number and type of samples to be used in both situations are determined by the projected budget for the site investigation and by estimated analytical costs and not by a judicious consideration of the acceptable error rates in making basic decisions (i.e. false positives and false negatives).

A rationale has been developed for how to determine the number, type, and placement of QA/QC samples.\(^6\) The decision-making process for determining how extensive a QA/QC program needs to be for a particular investigation is not simple. A stepwise process needs to be developed in which data from the QA/QC effort are progressively examined and compared with the sample data and to DQOs. Basic concepts need to be understood and applied to ensure that the data collected meet the needs of the decision maker.

Data that are collected as part of an environmental investigation are going to exhibit variability. The expectation is that variability associated with the measurement process is sufficiently low that variability in the data can be attributed to the measured parameters or population. QA/QC programs are implemented to assess and control measurement variability, but these efforts are frequently insufficient or unable to assess or control all of the sources of bias and variability throughout the measurement process. Often, the QA/QC programs are targeted towards the analytical phase of the measurement process, but considerable bias and variability may be present in other areas.

As reported in the “Rationale” document,\(^6\) Equations (1) and (2) are valid:

\[
\sigma^2_T = \sigma^2_M + \sigma^2_P
\]  

where \(\sigma^2_T\) = total variability, \(\sigma^2_M\) = measurement variability, and \(\sigma^2_P\) = population variability, and

\[
\sigma^2_M = \sigma^2_S + \sigma^2_H + \sigma^2_P + \sigma^2_A + \sigma^2_B
\]  

where \(\sigma^2_S\) = sampling variability (standard deviation (SD)), \(\sigma^2_H\) = handling, transportation and preparation variability, \(\sigma^2_P\) = preparation variability (subsampling variability), \(\sigma^2_P\) = laboratory analytical variability, and \(\sigma^2_B\) = between batch variability (note: it is assumed that the data are normally distributed or that a normalizing data transformation has been performed).

Bias can change over time and become intertwined with imprecision – both of these contribute to variability in the measurement process. A variety of QA/QC samples may be used in a rigorous manner to try to assess the magnitude and source of errors in the sampling of soils at hazardous waste sites. Some of the errors may never be assessed because the true distribution and concentration of contaminants in the environment can never be truly measured; they can only be estimated. The best approach is to try to minimize bias and imprecision at the outset by carefully considering and selecting the sample collection, sample preparation, subsampling, and analytical techniques that are apt to produce “representative” data with low measurement error.

Some of the most common QA/QC samples used during the collection of soils include field evaluation samples, field blanks, field duplicates, and preparation splits. Field evaluation samples (e.g. performance evaluation materials or site-specific soil QA materials) are soil samples of known concentration that are subjected to the same manipulations as routine samples. The field evaluation samples should be introduced in the field at the earliest stage possible. These samples can then be used to estimate total measurement error and, if they are used in duplicate, precision estimates can be made.

Field blanks provide a measure of various cross-contamination sources, decontamination efficiency, and other potential sources of error introduced from sources other than the sample. Three common types of blanks used in the field include the field rinsate blank, preparation rinsate blanks, and trip blanks. Rinsate blanks (i.e. equipment blanks) are used to assess the efficiency of the decontamination process. These blanks are obtained by pouring deionized/distilled water over the sampling equipment (for the field rinsate blank) or preparation equipment (for the preparation rinsate blank) after it has been decontaminated and then collecting the rinsate for analysis. Trip blanks are generally used during the collection of VOCs. A trip blank consists of the sample containers filled with deionized/distilled water, solvent (e.g. methanol), or evacuated vials used during headspace analyses. For some sampling efforts (depending on the DQOs), a portion of the trip blanks will be opened in the field (excluding evacuated vials) to assess if there is any contamination that may have occurred during sampling, preparation, or shipment to the analytical laboratory. The remainder of the trip blanks will not be opened in the field and can be used to assess contamination due to incomplete sealing of volatile organic analysis (VOA) vials and sampling jars or improperly cleaned glassware.
The field duplicate sample is an additional sample taken near a routine field sample and may be used to determine total within-batch measurement variability although differences in the two samples may also be attributable to short-range spatial variability in the soil. If the data from field duplicates are significantly different from the corresponding routine sample, then there is good cause to question the representativeness of the routine sample data and to employ data from other QA/QC samples to determine whether the problem is with short-range spatial variability. If the problem seems to be associated with short-range variability, then a larger support, or compositing of the samples on a small, spatial scale, may be all that is necessary to obtain more representative samples.

Preparation split samples are soil samples that are collected after the soil has been properly homogenized and, thus, all portions of the sample have theoretically equal concentrations. The preparation split samples are used to estimate the sum of subsampling, analytical, and data-handling error variations (i.e. total within-batch error minus the error that occurs during sampling, handling, transportation, and preparation/homogenization).

4 SAMPLING NETWORK DESIGN

A successful sampling design accomplishes the objectives of the investigation at minimal cost. The DQO process is one approach that provides a sound framework for sampling network design. The DQO process accomplishes three critical tasks. First, the DQO process develops a clear, quantitative statement of the decision that must be made. This is generally in the form of an if–then–else decision rule: if the sample measurements exhibit characteristic \( x \), then take action \( a \); else, take action \( b \). Second, by specifying tolerable error limits on the decision, the DQO process allows for the fact that the true concentration in volume \( v \) is never precisely known. Finally, the design-performance diagram can be used to evaluate the expected performance of alternative sampling design options and to select from among the acceptable designs the one with the lowest associated cost.

In the DQO approach, error limits are established across the entire range of possible contaminant concentrations, and can be plotted against true concentration to form a “design-performance” diagram (Figure 3). The acceptable range of performance is the area including

![Figure 3](image-url)
the gray region and the tolerable false-positive and false-negative regions. Each sampling scheme has an associated performance curve that shows the probability of making a correct or incorrect decision at any given true concentration. The performance curve (also known as a power curve) shown as the solid line in Figure 3 represents a sampling scheme that has acceptable performance because it falls within the specified limits. This particular curve also represents a minimum cost design because it meets but does not exceed the specifications. A sampling scheme with fewer samples or less accurate measurement would have higher error rates and be unacceptable, while a scheme with more samples or higher quality measurements would be acceptable, but unnecessarily expensive.

It is not easy to develop design-performance criteria. Determining acceptable decision error rates is a subjective process that is difficult and uncomfortable for many people to perform. There is a tendency to initially set the error rates so low that they lead to unacceptably high sampling costs, in which case the process must be repeated to obtain a more reasonable sampling design with lower overall associated costs.

### 4.1 Basic Spatial Sampling Strategies

To illustrate some of the basic spatial sampling strategies, two common decision scenarios in soil remediation will be examined. Additionally, alternative sampling strategies under the same decision scenarios will be discussed.

The first decision scenario involves the estimation of the mean concentration of contaminant in a specified volume of soil. Assume that a single distribution unit, or stratum, has been identified, such as the sediment in an abandoned waste lagoon, and that the decision maker will have to remediate the sediments if the mean concentration exceeds a specified threshold. From a design-performance diagram it has been determined that a sampling design will be acceptable if it the standard error (se) of the mean is ≤4, or equivalently, a variance (V哥伦) ≤16 (note: 

\[ \text{se}^2 = V哥伦 \]) . Further, assume that the measurement error variance (V哥伦) for collecting and analyzing a soil core is 10 and the population variance (V哥伦) is 90 (i.e. 10% of the total variance is due to measurement error including sample collection, preparation and analysis while 90% is due to natural variability at the site). The total variance (V哥伦), including measurement error, is given by Equation (3):

\[ V哥伦 = V哥伦 + V哥伦 = 100 \]  

For this scenario, a soil core costs $25 to collect in the field and $300 to analyze in the laboratory. The question that needs to be answered is, “What is the best sampling design?”

The classical approach to estimating a population mean is by the arithmetic mean of a random sample. Random sampling is always a valid method, even though it may not always be the most efficient for spatial sampling. In the random sampling approach, it is simple to calculate the standard error of the mean and evaluate the costs of alternate sampling schemes.

For a random sample of N measurements, the variance of the error of the mean (V哥伦) is simply equal to V哥伦/N. The design process now involves nothing more than finding the smallest value of N that will meet our example design requirement, namely, V哥伦 ≤16. In this case, N = 7, making V哥伦 = 100/7 = 14.3, which is <16. The final cost of the random sampling design is 7 × $325 = $2275.

The bulk of the cost in the case of this random sampling design is due to laboratory analysis, so let us next consider a less expensive alternative. Assume that an alternative laboratory method is available at a cost per analysis of $100, but that this method is less precise, with V哥伦 = 40 instead of 10. If the initial study objectives were to obtain high-quality measurements of individual soil cores, this approach would not be useful. By taking four separate measurements of a single core sample, V哥伦 could be reduced to V哥伦/4 = 40/4 = 10 and equal the precision/quality of a single measurement by the original method. However, the cost of the replicated analyses would be $4 × $100 + $25 = $425 per sample, which is more expensive than with the original method selected. However, the original decision rule has nothing to do with measuring individual cores, only with estimating the mean of the sediments in the waste lagoon. For this purpose, V哥伦 = V哥伦 + V哥伦 = 90 + 40 = 130. To meet the required objective, nine measurements would be needed so that V哥伦 = 130/9 = 14.4 < 16. The cost of this design alternative becomes 9 × $125 = $1125, a substantial financial improvement from the $2275 cost of the initial random sampling design with the more precise (but more expensive) analytical method.

Suppose that with the initial measurement method, where V哥伦 = 10, the population variance is much higher than the measurement variance. In such cases, composite sampling can be a cost-effective alternative approach. In composite sampling, individual core samples are physically combined to make a single unique sample from which one or more measurements of the sample can be made. The overall estimation error is V哥伦 = V哥伦/N哥伦 + V哥伦/N哥伦, where N哥伦 is the number of cores or increments that make up a composite sample and N哥伦 is the number of analyses performed on a single composite sample. There will also be an additional error component and an added cost introduced by the process of homogenizing and subsampling the composite, but for this example it is assumed that this added error and cost
are negligible. The problems associated with subsampling a composite sample are far from trivial and will be discussed in detail in section 7.1.

The composite sampling design process becomes one of evaluating combinations of \( N_c \) and \( N_a \) and selecting the lowest-cost combination that meets the initial design requirements. In this case, the best result is obtained when \( N_c = 15 \) and \( N_a = 1 \) (i.e., a single analysis of a 15-core composite sample). The error associated with the alternative approach would be \( V_e = 90/15 + 10/1 = 6 + 10 = 16 \), and the associated cost is \( (N_a \times $300) + (N_c \times $25) = $675 \). This achieves the original objectives at a lower cost than with individual samples.

From these examples, it has been shown that an improvement on the original design can be achieved by using a lower-cost analytical method or by compositing. Can the project planners do even better by combining both methods and analyzing composite samples by the cheaper method? Interestingly, in this particular example, the answer turns out to be no. With a single composite sample, measurement error \( (V_m) \) is again a significant factor, and the cost of reducing \( V_m \) through multiple analyses becomes cost prohibitive. The best option to meet the original goal of \( V_e \leq 16 \) is with \( N_c = 15 \) and \( N_a = 4 \) (where \( V_e = V_p/N_c + V_m/N_a = 90/15 + 40/4 = 6 + 10 = 16 \)), for a total cost of $775 [equals \((15 \times $25) + (4 \times $100)]\. Although this approach costs slightly more than the single, more precise analysis ($400 vs $300), the four replicate analyses on the composite sample provide at least some measure of QA in terms of precision (laboratory analytical repeatability).

The example above was intended to illustrate the type of economic analysis of sampling alternatives that is part of the DQO process, not to provide a blanket endorsement of composite sampling or cheap but imprecise analytical methods. With different costs, variances, and objectives the conclusions could be completely different.

4.2 Estimating Variances

While the analysis described above is relatively simple, the results are only strictly true if all of the assumptions are correct. The major assumptions were:

- the variance of the population distribution and the measurement error distribution for each measurement alternative are known;
- the true costs of sample collection and measurement are known; and
- all measurements are independent of each other.

In practice, these assumptions are at best only approximately true, so it is worth looking at how they affect the analysis of sampling alternatives. The relative magnitude of the variance of the population versus the variances of the alternative measurement methods and the relative costs of the alternatives are all important in determining the overall sampling strategy. Generally, the relative costs of measurement methods can be estimated reasonably accurately. The more difficult problem is estimating the error variances. The true variance of a contaminant in soil at a site or within a stratum will always remain unknown. The best way to estimate it is through the analysis of sample data, but this poses a dilemma. It is more difficult to estimate variances precisely than it is to estimate means. It is likely that by the time one has collected enough samples to obtain a satisfactory estimate of variance, there will be far more data than are needed to estimate the mean efficiently. The situation becomes worse if composite sampling or another alternative measurement method were evaluated since an estimate of the measurement variance(s), in addition to the total variance, is needed. Analytical variances are often well known, but measurement variance includes many sampling and subsampling error components that are site-specific. Estimating measurement variance from sample data requires the analyses of multiple field replicates. Estimating these variances can easily cost many times more than simply estimating the mean.

The alternative to estimating variances from data is to estimate them through educated guesswork (i.e., best professional judgement). Usually, at least a few measurements will be available from previous investigations which can in turn be used to estimate the measurement variance. Analogies can be made with data sets from other similar sites. Measurement variance can likewise be estimated from QA data collected at similar sites, or it can be estimated by combining the analytical variance from laboratory studies with estimates of preparation and subsampling variances from particular sampling theory (as described later).

The question of which approach to take to estimate the variances should be addressed as part of the DQO process. In addition to determining the decision to be made and how accurately it must be made, it is also necessary to know how accurately the decision maker needs to know how accurate the decision is. Unfortunately, there is no standard formula for determining these requirements. In the example above, if the single-composite, single-analysis option is chosen, there will be no way to evaluate whether or not the desired precision is achieved. The driving factor will be the magnitude of the consequences of decision errors. Suppose in the above example that the variances were preliminary estimates based on prior investigations of similar sites. Suppose, also, that the decision involved is relatively minor, for example, whether to leave slightly contaminated soil in place or remove it to a municipal landfill at a cost of $5000–$10 000. In this situation, the
analysis described above might well be sufficient, and one of the compositing schemes discussed would be chosen. However, if the decision were between disposal in the municipal landfill versus in a hazardous waste facility at a typical cost of $100,000, it is reasonable to spend more money on sampling in order to be more confident about the quality of the decision. Again, there is no unique simple strategy for such cases; nonetheless, some form of sequential sampling may be appropriate.

In sequential sampling, an initial set of data is collected and evaluated. The decision to be made is now threefold: yes, remediation is required; no, the soil is “clean” and can be left in situ; or collect more data to help define the situation better. The initial data are used to estimate the mean, variance, and standard error, and if the standard error is low enough, the decision is made. If the standard error is too high, the variance is used to estimate how many additional samples are needed in the second sampling phase. The process is repeated until a confident yes or no decision can be made. The number of samples collected in the initial set is determined by economics and logistics. If measurements are being made in the field, it may be practical to re-evaluate the data after each measurement. This approach minimizes the total number of samples required. However, if the samples must be sent to a laboratory for measurement, there are time delays and mobilization costs each time a sampling crew returns to the field. This may make it advantageous to make a conservative initial estimate of variance and attempt to oversample the initial phase to avoid further sampling.

Sequential sampling can be used with either individual or composite samples. Unfortunately, economic analysis of the alternatives is very difficult, especially when the population is not normally distributed. Real-world distributions of contaminated soil measurements are often highly skewed and contain non-detects (i.e. data below the instrument or method detection limit (DL)). In such cases, the only practical method for comparing the cost-effectiveness of alternative sequential designs is through elaborate computer simulations of the sampling process. Composite samples may well have an advantage in that the composite samples will be more normally distributed than the original population. The occurrence of a more normally distributed population makes it more likely that normality-based tests, such as Student’s t-test, can be used with a small number of measurements.

4.3 Spatial Dependence
In the examples above, it was assumed the data were independent. However, the fate and transport of contaminant in soil are determined by physical and chemical processes that do not operate at random. This is also true of natural soil parameters, such as clay content and porosity, that can influence the spatial distribution of contaminant. In general, it is expected that soil measurements taken a few centimeters apart would be more similar in concentration than when the measurements are taken kilometers apart. Quantifying such spatial dependence and how it affects sampling and estimation is the subject matter of geostatistics. The reader is referred to Isaaks and Srivastava(1) for a practical introduction to geostatistics. Additionally, Webster and Oliver provide an excellent discussion of the specifics involved in spatial dependence during soil sampling applications. Only a brief discussion of the basic concepts and a few rules of thumb for sampling and estimation will be provided in the following text.

Spatial dependence can be quantified in the form of a semi-variogram (Figure 4), which shows the variance of measurements as a function of the spatial vector (distance and direction) separating the points. More precisely, the semi-variogram shows the expected value of \[ \frac{(z(x) - z(x + h))^2}{2} \] where \( z \) is the analyte concentration at points \( x \) and \( x + h \), and sampling location \( x + h \) is separated from sampling location \( x \) by the vector \( h \). The semi-variogram incorporates all of the components of the total variance. The \( y \)-intercept at \( h = 0 \) includes all of the independent measurement variance components, such as field and laboratory preparation, subsampling, and analytical error (AE). The semi-variogram at very small \( h \) values (i.e. very small distances from the original sampling location) would reflect the variance of collocated samples. The shape of the semi-variogram curve defines the spatial dependence structure. The mean value of the semi-variogram over all possible sample pairs at all possible separation vectors is simply the total population variance. The semi-variogram provides a very useful model of both

![Figure 4](https://example.com/variogram.png)  
**Figure 4** A typical semi-variogram showing the variance of measurements as a function of the spatial vector (distance and direction) separating the data points.
independent and dependent variance components, but like any of the components, creating a semi-variogram entirely from data can be very expensive.

When data are spatially dependent, the arithmetic mean is no longer the best (minimum error variance) estimate of the population mean. Instead, a weighted mean should be used. In geostatistics, a weighting method called kriging is frequently used, in which the semi-variogram is used to compute sample weights that minimize the estimation variance. When two or more samples are clustered very closely together (i.e. the sampling distance between two points is small), whether by chance or by design, they are effectively providing duplicate information. This duplication is indicated by low semi-variogram values among neighboring samples and smaller weights are assigned to such samples. Conversely, samples with no near neighbors receive higher weights. By down-weighting clustered data that are duplicative, kriging provides better estimates than simple averaging.

The most efficient sampling design, when spatial dependence exists, is one that minimizes the duplication of information or, equivalently, maximizes the distance from each sample to its nearest neighbor. The solution to this problem is simple: use a systematic sampling scheme and sample at regular grid nodes. Webster and Oliver(9) have shown that grid sampling can be significantly better than random sampling in some cases. They also reported that the arithmetic mean of a regular grid is essentially equivalent to the kriged mean for the same data set. This suggests that regular grids are also optimal for composite sampling where the physical mixing of the soil cores is equivalent to arithmetic averaging. Triangular grids are the most efficient (in two dimensions) but square grids are very nearly as good and are generally more convenient in the field. Since it is usually safe to assume the existence of some form of spatial dependence in soil contamination, regular grid sampling is recommended, preferably with a random origin and orientation.

4.4 Sampling for Local Estimation

The purpose of local estimation is usually to classify a site into higher-concentration areas that need some form of remedial action and lower-concentration areas that need none. When it is assumed that the site contains high-and low-concentration areas, it is the same as saying that there is spatial dependence (i.e. similar values tend to be grouped together). This spatial dependence becomes a significant factor in sampling network design. Similar to global estimation, sampling on regular grids is more efficient for local estimation.

Local estimation and decision making can become very complex. It is critical to establish a very clear decision rule at the beginning that must include the scale of the decision. The simplest approach to local estimation is to subdivide the site into an array of discrete units. These discrete units may be as large as exposure units or as small as remediation units. Generally, high remediation costs lead to the consideration of smaller decision units in an attempt to be more selective in which units must undergo the expense of being remediated. Each unit will be classified based on an estimate of its mean concentration. Subdividing a site into smaller remediation units means that many decisions will be made instead of just one and that the consequences of error for any given decision become much smaller. The DQO process should reflect this by establishing broader error tolerances for smaller units.

Composite sampling remains an attractive option for local estimation because compositing increases the area represented by each sample and reduces the sample variance. Compositing is particularly effective when individual core concentrations vary greatly over distances that are small compared with the scale of decision, and when this short-range variability is high relative to measurement error. Generally, the larger the area over which a composite is taken, the greater is the reduction in sample variability; however, the composite area should not be larger than the decision unit.

Local estimation differs significantly from global estimation because the local unit being estimated is a part of the larger population. As a result of spatial dependence, each unit is correlated to some extent with its neighboring units. It becomes possible to estimate the concentration of a unit by interpolation from nearby data, even when there are no samples in the unit itself. In this case the design problem is no longer one of adequately sampling each unit, but rather one of sampling the population area in order to adequately estimate each unit.

There are two basic approaches to optimizing sampling designs for local estimation. Both require an estimate of the semi-variogram. The first approach is based on the fact that when estimates of remediation units are made by kriging, estimates of the corresponding standard errors are also produced. The basic assumptions involved in kriging result in the standard error estimates being determined by only the semi-variogram and the sample locations, not by the data values, so it becomes possible to calculate kriging standard errors for hypothetical sampling network designs. The performance of alternate designs can be compared with the established decision error limits. The approach is detailed by McBratney et al.\textsuperscript{(9)} and McBratney and Webster.\textsuperscript{(10)} The major problem with this approach is that kriging estimates of kriging standard errors are sensitive to errors in estimating the semi-variogram and to errors in the basic assumptions.

A promising alternative approach to the problem of developing complex designs for local estimation was
described by Englund and Heravi.\(^{(11,12)}\) This approach involves first creating a detailed computer model of the soil contamination distribution that is consistent with both the semi-variogram and with any available data using a geostatistical technique called “conditional simulation”. The resulting model contains a very dense grid of data points (typically, 10,000 or more points.). A few of these grid points will contain actual measured data values while the remainder of the grid points will contain simulated measurements that are both reasonable and realistic in detail. This approach is less sensitive to errors in estimating the semi-variogram because the model is forced to fit the actual data values. After the detailed model has been constructed, it is possible to simulate the entire process of sampling, estimation, and decision making for any particular sampling design and to compare the cost-effectiveness of alternative designs. The basic procedure for evaluating a sampling design by conditional simulation is as follows:

1. Overlay a grid of decision units over the modeled area. Each unit will contain many simulated sample values.
2. Calculate the mean concentration of all the simulated values in each unit. These are the true concentrations of the units. Comparing these means to a specified action level determines what the correct remediation decision for each unit should be.
3. Select a sampling design scheme, such as 50 samples at randomly selected locations over the model area.
4. Determine a set of sample locations and draw the simulated sample concentration values from the model.
5. Estimate the mean concentration of each decision unit, apply the decision rule, and determine whether the decision is correct by comparison with the true concentration from step 2.
6. Repeat steps 4 and 5 at least 100 times with different sample sets generated by the same sampling scheme and keep track of all decisions obtained.
7. On a design-performance diagram, plot the proportion of correct decisions versus the concentration for each of the decision units. If all of the points fall within the design-performance limits, the sampling scheme is deemed acceptable.

The conditional simulation procedure is complex and clearly best suited to large, expensive remediation projects. Its primary advantages include the flexibility to evaluate alternate spatial designs, such as regular grids and composites, to tabulate detailed performance statistics, such as costs of sampling and remediation, and to quantify the amount of contaminant that would remain unremediaged following the selected sampling design.

This simulation approach can also be used to evaluate the cost-effectiveness of the overall sampling/remediation strategy. In a design-performance diagram like that in Figure 3, the right-hand boundary of the “acceptable performance” zone limits the probability that highly contaminated soil will remain unremediaged, while the other boundary limits the probability that relative uncontaminated soil will be unnecessarily remediaged. The former is of primary interest to the regulator because it protects against risk to humans and the environment. The latter boundary, however, is primarily an economic choice on the part of the party responsible for remediation. The trade-off is between sampling and remediation costs. In practice, the actual decision level will occur at estimated concentrations near the center of the gray region. Moving the left-hand boundary further to the left lowers the effective decision level and increases the amount of remediation to compensate for the greater uncertainty due to less sampling. Moving it to the right raises the effective decision level and increases the amount of sampling required. Simulation can be used to evaluate these trade-offs and find the most cost-effective solution that meets the regulatory requirements.

5 DOCUMENTATION

Accurate documentation is essential for the success of a field sampling program. Documentation should occur in all phases of a soil sampling program, including planning, sample collection, and laboratory analysis. Three documents usually required are the field sampling plan (FSP), quality assurance project plan (QAPP), and health and safety plan (HASP). The FSP provides guidance for all fieldwork by defining in detail the sampling and data-gathering methods to be used on a project.\(^{(13)}\) Topics that should be discussed in the FSP are the site background, sampling objectives, sample location and frequency by matrix (including QA/QC samples), sample designation, sampling equipment and procedures with standard operating procedures (SOPs), if available, and sample handling and analysis. The QAPP describes the policy, organization, functional activities, and QA/QC procedures necessary to achieve the DQOs defined for the project. The detail to be included in QAPPs depends upon the category of investigation being undertaken. For example, investigations that have compliance or litigational implications require discussion of the following 14 points: project description; project organization and responsibilities; QA objectives; site selection and sampling procedures; sample custody; calibration procedures.
and frequency; analytical procedures; data reduction, validation, and reporting; internal QC checks; performance and system audits; preventative maintenance; calculation of data quality indicators; corrective action; and QC reports to management.\(^\text{14}\) If both a FSP and QAPP are required for the same project, to avoid duplicative efforts for sections that contain the same information, it is recommended simply to reference the overlapping section in the one document from the other document. The HASP is prepared as a support document to protect the health and safety of the soil sampler and to meet United States Occupational Safety and Health Administration (OSHA) guidelines and regulations.\(^\text{13}\) Topics to be discussed in a HASP include identification of key health and safety personnel (e.g., site health and safety officer); hazard risk analysis by task and operation; employee training requirements; personal protective equipment (PPE); medical surveillance requirements; frequency and types of air monitoring; site control measures, decontamination procedures; SOPs for the site; emergency response procedures; and confined space entry should sampling be performed in a pit or hole.

During sampling and analysis, it is only through proper documentation that a soil sample can be linked with a sampling location (including depth) and the date and time of collection. Use of detailed field and laboratory logbooks to document routine information (e.g., sampling date, weather conditions, sample numbers, QA/QC sample use, air monitoring data), problems encountered during sampling (e.g., inability to penetrate to desired depth), sampling location changes, site characterization information (to be discussed), soil characteristics, production of the site map (to be discussed), or analytical procedural changes. The use of standardized forms greatly enhances field documentation by ensuring the collection of complete information required at the site. Other required documentation associated with sample identification and shipment include sample labels, chain-of-custody forms, custody seals, and shipping airbills.\(^\text{15}\)

6 SITE CHARACTERIZATION

Whenever a soil sampler, sampling team, or management team approaches a new site that needs to be evaluated, one of the initial steps performed should be site characterization (i.e., site description). A good site characterization program consists of two major steps, namely site observation and subsequent site mapping. Site characterization may be limited to a reconnaissance survey or involve a full-scale (or definitive) survey. A reconnaissance survey is performed to confirm historical data through the collection of a few selected soil samples for analysis or to identify site features that may indicate contaminant sources, pathways, affected populations, and potential monitoring/sampling locations. A full-scale survey is undertaken to obtain soil samples for analysis with their results being used in the final decision-making process.\(^\text{16}\)

For both survey types, a basic suite of characteristics should be noted and recorded during the site visit. This suite includes information and observations on climate and weather, slope, surface erosion and erodibility, surface runoff potential, vegetation, and the presence of macro- and mesofauna. Although these parameters are readily observed, they should be recorded because they may provide explanations for observed trends in the data and possible considerations for long-term planning and remediation efforts at the site.

In addition to the site characteristics, numerous soil characteristics should be examined and recorded in the field since they provide information on potential subsurface transport pathways, variability of soil properties, location of contaminants, and identify features that may influence remedial operations. More complete descriptions and information on site characteristics may be found in Cameron\(^\text{17}\) and Boulding.\(^\text{18}\)

6.1 Site Observations

Climate and weather are site characteristics that often influence the collection of soil samples. Climate, the average condition of the weather over a period of years, influences the time of year that sampling and site remediation efforts can occur.\(^\text{17}\) Clearly, soil sampling during the winter months in the northeastern United States may be restricted owing to cold weather and frozen ground conditions, yet in contrast, winter sampling in the southwestern United States may be preferable to avoid the extreme high temperatures commonly encountered during the summer months. Weather conditions, the state of the atmosphere during the field investigation, influence the specific time of sampling. Specific conditions to note include temperature, precipitation, wind speed and direction, and humidity. Although often noted, but not recorded, these conditions generally influence the health and safety of the sampler and have little direct influence on soil sample collection with the exception of precipitation. For example, when the wind is blowing, samplers should always position themselves upwind to avoid inhalation of dust and other particles that may contain the contaminants of concern. During times of high winds, sampling should be avoided to prevent the spread of the contaminants sorbed on fugitive dust particles leaving the waste site.

It is important to note the slope of the soil surface because it influences the rate and amount of runoff and erosion of water, soil, and associated contaminants.\(^\text{17,19}\)
Slope features to be noted include gradient, length, shape, and topographic position. Simple terms such as flat, moderate, or steep can be used to describe the gradient. If greater accuracy is required, slope gradients may be recorded as a slope percentage (the change in elevation per horizontal distance between two points) or a slope angle (measured in degrees from horizontal). Slope length, usually measured in meters or feet, influences the behavior of water and the potential for erosion. In general, longer slopes have greater runoff and erosion potential than shorter slopes. Slope shape (e.g. convex, concave, or flat) and topographic position (e.g. summit, shoulder, sideslope, or floodplain) influence the movement of water and soil on the surface and in the subsurface. For example, steep convex shoulder positions are more likely to experience erosion than flat or concave floodplains in which soil deposition is likely to occur.

Site characterization of surface erosion is important to assess soil loss or deposition in the past and to assess future erosion potential. The determination of surface erosion is easily done visually by comparison of observed changes in soil texture and color between surface and subsurface horizons. If subsurface colors or textures are noted at or near the surface, then that area has undergone and is prone to erosion. The presence of rills, gullies, or other erosional features also indicate that erosion is occurring at the site and mark potential pathways for movement of contaminated soils within and from the site. Valuable information on surface erosion and erodibility of soils at a site can be found in county soil surveys published by the United States Department of Agriculture (USDA) National Resource Conservation Service (NRCS), formerly the USDA Soil Conservation Service.

Surface runoff potential is used to evaluate the potential for transport of contaminants at the soil surface to surface streams or other water bodies. The runoff potential is controlled by slope and saturated hydraulic conductivity. Saturated hydraulic conductivity may be defined as the rate of movement of water through a soil or as a measure of the ability of a soil to transmit water under saturated conditions. Runoff is directly proportional to slope (i.e. as slope increases, surface runoff potential also increases) and inversely proportional to the saturated hydraulic conductivity (i.e. as the hydraulic conductivity increases, the runoff potential decreases). Similarly to surface runoff, valuable information on soil hydraulic conductivities and surface runoff may be found in soil surveys published by the USDA NRCS.

Vegetation serves as an indicator of site history, erosion potential, and contaminant location. During site characterization, the sampler should observe the nature (e.g. hardwood forest), kind (e.g. maple trees with mixed understory), extent (e.g. dense, scattered, sparse, or bare), and distribution of the site vegetation. The presence of stunted vegetation, luxuriant plant growth in comparison with surrounding areas, discolored leaves, and “burn” spots can all indicate the toxic effects of contaminants in the soil. In areas of heavy metal contamination, sampling of vegetation along with soil sampling may be desirable to assess potential metals exposure through bioaccumulation. Macro- and mesofauna, like vegetation, can provide an indication of the presence of contaminants. Additionally, during their routine daily activities, fauna create potential pathways to enhance vertical movement and leaching of contaminants to depth within a soil, mix the soil, and are capable of moving large quantities of subsurface materials to the surface. Macrofauna are those animals that can be measured in centimeters (or inches) such as burrowing rodents, earthworms, and insects. In contrast, mesofauna are the smaller animals including other insects, arthropods, nematodes, and smaller worms. Simple terms, such as many, common, few, and none, can be quickly recorded to indicate the presence of indigenous fauna. A lack of any visible fauna may indicate an area of high contaminant concentrations.

6.2 Site Mapping

The second step in the site characterization process is the production of a site map. Site mapping generally occurs in two phases: initial and final mapping. The site map is important because it allows for planning sampling locations and allows for the subsequent plotting of the contaminant spatial distribution. The initial site map is a crude sketch of the sampling site. Features that should be drawn on the site map include both permanent and “temporary” objects. Permanent objects to be mapped include playgrounds, buildings, roads, railroads, boulders, and bodies of water (e.g. streams or rivers). Temporary objects include trees, fences, power poles, and telephone poles. Drainage ways (e.g. gullies or depressions) are sometimes plotted since they represent potential pathways of contaminant migration. Other features that may be included on the initial site map are bare spots, percentage vegetative cover, and unusual surface features such as soil discolorations and surface staining.

Once the first draft sketch of the site has been completed, the approximate locations of the sampling points can be plotted based on the sampling design. More exact locations of the sampling points can be made using surveying equipment or global positioning system (GPS) units depending upon the needs of the program. It will be from these marked points that the sampler(s) will collect the soil samples. If changes in sampling location need to be made owing to unmapped surface features
or unforeseen subsurface obstacles (e.g. large tree roots, buried rocks), the sampler should indicate the type of obstacle encountered, move approximately 30 cm (12 in) in any direction away from the obstacle, and try to re-collect the sample. This process may have to be repeated several times in different directions from the initial point or at greater distances until a satisfactory location is found. The new sampling point should be marked on the site map to indicate the sampling location change.

After sampling has been completed, the final location of each sampling point needs to be accurately determined. Exact locations of the final sampling points can be made through a variety of different techniques ranging from measuring the distance and direction from a fixed reference point (or points) with tape measures, through the use of field survey equipment and GPS units. Each sampling point should be reconfirmed as to its approximate spatial location in the field and on the site map. A more formal site map may then be produced using this collected information in conjunction with, or separate from, the analytical results.

7 SAMPLE COLLECTION

After the site has been adequately mapped and all important site observations have been noted, the next step is to collect the soil samples. It is often quoted that it is during sample collection that a majority (80% or more) of the total measurement error occurs and yet it is during this phase of a program that the least attention to detail is paid by the decision makers, project managers, chemists, etc. The following text provides guidance on how to collect a soil sample properly, taking into account all the potential pathways for error to enter the system, provides means to minimize these errors, provides information on common concerns during the selection of sampling equipment, and discusses the advantages and disadvantages of commonly available sampling tools.

7.1 Particulate Sampling Theory

A particulate sampling theory was developed by Pierre M. Gy for the mining industry to provide a more accurate and precise means for identifying heterogeneous ore grades. The theory is based upon the relationship that exists between the variability of the material, the particle sizes within the material, the distribution of the component of interest (e.g. pollutant), and the size of the sample collected. Particulate sampling theory is based on sampling “correctness”, which in turn is based on a property intrinsic to the material itself and the equipment used to extract the sample. Gy defines a correct sample as “A sample in which all particles in a randomly chosen sampling unit have the same probability of being selected for inclusion in the sample”. The importance of this theory to environmental soil sampling is that the theory identifies various sources of error that can influence the final determined contaminant concentration and presents the means for controlling these errors. The following text is a very brief synopsis of Gy’s particulate sampling theory as it pertains to soil sampling. A more complete and in-depth discussion of all aspects of the sampling theory may be found in Pitard.

Two models are described in Gy’s particulate sampling theory: a continuous model which deals with variables through time and space and a discrete model which addresses sampling populations of fragments. Since soil sampling is more closely related to sampling populations of discrete fragments, only those errors associated with the discrete model will be discussed. The errors associated with the discrete model include the fundamental error (FE), grouping and segregation, short-range heterogeneity, increment delimitation, increment extraction, preparation, and AEs.

7.2 Sources of Variation and Sampling Error

One of the key concepts of Gy’s particulate sampling theory and its determination of the FE is that the relationship between the maximum particle size in a collected sample and the weight of the sample to be collected must be clearly defined. By following the equations (to be presented), the sampler can select a particle size range that will reduce the relative variance in the final results to an acceptable level (as defined in the DQO process) and ensure that enough soil is collected to present an unbiased sample to the laboratory for analysis.

The FE is associated with the natural variability inherent (i.e. the heterogeneity that is inherent to the composition of each fragment or particles making up the lot) in the composition of every particle making up the “lot” to be sampled. A lot is defined by Gy as the batch, volume, or sampling unit from which increments and samples are collected. Lots may range in size from a bottle of soil at the laboratory, to a dump truck load of soil, through the entire hazardous waste site under investigation. The FE is the only error that cannot be eliminated; however, it can be reduced by comminution of the maximum particle size or by taking larger sample sizes in the lot. Mathematically, the FE is defined as in Equation (4):

$$s_{FE}^2 = \left( \frac{1}{M_S} - \frac{1}{M_L} \right) IH_L$$

where $s_{FE}^2 = \text{relative variance of the FE}$, $M_S = \text{mass of the sample (g)}$, $M_L = \text{mass of the lot (g)}$, and $IH_L = \text{constant factor of constitution heterogeneity}$. When the mass of
the lot, $M_L$, is large in relation to the sample weight to be collected, $M_S$, the equation can be simplified to Equation (5):

$$s_{FE}^2 = \frac{IH_L}{M_S} \quad (5)$$

$IH_L$ can be estimated using Equation (6):

$$IH_L = fgced^3 \quad (6)$$

where $f =$ shape factor (dimensionless), $g =$ particle-size (or granulometric) factor (dimensionless), $c =$ mineralogical factor ($g \text{ cm}^{-3}$), $l =$ liberation factor (dimensionless), and $d =$ diameter of the largest particle (cm).

The shape factor ($f$) addresses the error due to all fragments not being perfect cubes and thus not fitting perfectly through the square holes in sieves used to screen the soil.\(^{22}\) The shape factor is influenced by the number of particles passing through two consecutive upper and lower sieves, average particle diameter, average particle density, and the mass of the fraction to be analyzed. Mathematically it is expressed by Equation (7):

$$f = \frac{M}{p}d^3\lambda \quad (7)$$

where $M =$ mass of fraction collected on the lower sieve (g), $p =$ number of individual particles, $d =$ average diameter of particles passing through the two sieves (cm), and $\lambda =$ average density of collected fraction ($g \text{ cm}^{-3}$).

For all practical purposes, a quick examination of the sample under a microscope is sufficient to determine the shape factor based on visual observation and comparison with the following approximate shape factor values. The shape factor used in calculating the FE can be approximated by using values of (a) 0.5 or slightly less for most minerals and soils, (b) 0.1 for flat minerals such as micas, and (c) $\geq 1$ for acicular minerals, such as asbestos and tourmalines. Shape factors as large as 10 may be used in the presence of long, thin, needle-shaped minerals.

The particle size distribution factor ($g$) addresses the error due to all fragments not being exactly the same size and thus not being the coarsest fragments in the sample.\(^{22}\) Mathematically, it can be expressed by Equation (8):

$$g = \sum \frac{M_{La}}{M_L} \quad (8)$$

where $M_{La} =$ mass of the size fraction ($a$) of concern (g) and $M_L =$ mass of the lot (g).

Two general assumptions for $g$ that can be made in calculating the FE are that for most soils, $g$ is approximately equal to 0.25 and that if the soil has been screened to a particular size fraction, then $g$ can be approximated by a value of 0.55.

The mineralogical factor ($c$), also known as the chemical or mineralogical composition factor, accounts for the maximum heterogeneity within the lot when the mineral (or constituent of interest, e.g. a pollutant) is completely liberated from the other material (gangue). It results from differing particle densities and associated differing concentrations.\(^{22}\) While the full mathematical equation accounts for the average concentration of the lot and the varying densities of the fraction of concern and the gangue or rest of the material, for most soils Equations (9) and (10) can be used:

$$c = \frac{\lambda_M}{a_L} \quad \text{if } a_L < 0.1 \quad (9)$$

$$c = (1 - a_L)\lambda_g \quad \text{if } a_L > 0.9 \quad (10)$$

where $\lambda_M =$ density of pure mineral or constituent of concern ($g \text{ cm}^{-3}$), $a_L =$ critical content (proportion of the constituent of interest in the lot) of the lot (dimensionless), and $\lambda_g =$ density of gangue or background materials ($g \text{ cm}^{-3}$). A particle density of $2.6 - 2.65 \text{ g cm}^{-3}$ is often used to represent the density of the soil in these equations. The critical content ($a_L$) of the lot is usually an approximation based on historical data about the proportion (or concentration) of the contaminant of concern at the site.

The liberation factor ($l$) is a correction factor taking into account that $c$ is a measure of the maximum possible heterogeneity where the contamination occurs as completely separated (liberated) discrete particles within the soil matrix.\(^{22}\) Hence $l$, whose values lie between 0 and 1, adjusts for heterogeneity of the sample or lot. Mathematically, it is expressed by Equation (11):

$$l = \frac{a_{max} - a_L}{1 - a_L} \quad (11)$$

where $a_{max} =$ maximum proportion of the pollutant associated with the largest contaminated particles in the lot and $a_L =$ average proportion of the pollutant in the lot.

The liberation factor can be estimated depending upon the degree of visual heterogeneity within the sample using values of 0.8, 0.4, 0.2, 0.1, and 0.05 for matrices that appear to be very heterogeneous, heterogeneous, average, homogeneous, and very homogeneous, respectively. At most hazardous waste sites where soil contamination is the result of a spill, $l$ values range between 0.05 and 0.2. In contrast, where discrete contaminant particles have been spread out at a site (e.g. ground Pb plates from used automotive batteries), then a liberation factor of between 0.8 and 1 may be appropriate.

The final and perhaps most influential factor used in the determination of the FE is the diameter ($d$) of the opening of a square mesh retaining no more than 5% of
the sample. The largest particles strongly influence the FE because they have the greatest inherent heterogeneity among particles.

By knowing the factors that control the FE, the sampler can minimize, but never eliminate, the FE. However, the FE is not the only source of error or bias that must be considered during the collection of a soil sample. The sampler must be careful to collect a “correct” sample and thus avoid introducing the other biases into the final results. These biases are the result of the grouping and segregation, increment delimitation, increment extraction, preparation, and AEs. Fortunately, these errors can be minimized or eliminated through the careful collection of the soil sample.

The grouping and segregation error (GE) results from the distributional heterogeneity, the heterogeneity that is inherent to the manner in which separate and distinct particles (or aggregates) are scattered or spread out within the lot to be sampled. The grouping factor reflects the number of increments (i.e. the group of particles extracted from the lot in a single operation of a sampling device) making up the sample compared to the number of fragments (i.e. particles, and AEs) making that sample. The grouping factor approaches zero as the number of increments approaches the number of fragments. The segregation factor accounts for the segregation of different types of particles and the natural range between the minimum and maximum distributional heterogeneity within a sample. The segregation factor ranges between zero and one. The major factor affecting GE is gravity. GE can occur due to gravitational separation that results from differences in:

- particle density;
- size;
- shape (e.g. round particles tend to move or roll more easily in the sample or pile than flat particles);
- magnetic properties (e.g. magnetite particles will preferentially tend to stick to themselves or steel sampling utensils);
- electrostatic charge (e.g. charges on the sides of plastic bottles or bags can cause the adhesion of charged clay particles);
- moisture, which tends to clump soil particles together;
- air turbulence during sample splitting or homogenization, which can cause loss of the fines;
- vibration (e.g. during transport from the site, on a laboratory cart, or from a vibrospatula used to obtain subsamples) in which heavy particles will slowly settle to the bottom of the sample container.

To minimize the grouping error, the collection of as many small increments as is practically possible is recommended. This process of collecting numerous small increments increases the probability of collecting all types of “groups” for inclusion in the sample, and thus reduces the grouping error. To minimize the segregation error, homogenization of the lot before sampling is recommended, taking care that the homogenization process itself is free from the factors that increase GE.

The short-range heterogeneity error (CE1) is a random, discontinuous error that is influenced by FE and GE (CE1 = FE + GE) and thus can only be minimized. CE1 is what most soil samplers are referring to when they discuss the “natural variability” of a soil through time or space and what geostatisticians call the “nugget effect”. Since CE1 is a random and discontinuous error, it can only be minimized by performing “correct” sampling and, thus, minimizing the factors that influence FE and GE.

Sampling is a selection process. The selection process can either be probabilistic (i.e. sampling with a random selection component) or nonprobabilistic. Nonprobabilistic sampling (e.g. grab sampling) can never be strictly “correct”. Probabilistic sampling can be “correct” or “incorrect”. Probabilistic sampling is correct when all of the constituents of the lot to be sampled have an equal probability of being sampled and when all constituents that are not of the lot have no probability of being selected. The error associated with the selection/sampling process is known as the materialization error (ME) and is the combination of the two relative variances, the delimitation error (DE) and the extraction error (EE); that is, ME = DE + EE. The ME must be minimized to approach the notion of correct sampling. [Note: although the preparation error (PE) (to be discussed) is technically part of the ME, it is usually treated separately.]

The increment DE can be a major source of sampling bias and results from incorrectly defining the boundaries or limits of the volume of material to be extracted and physically collected from the sample. In order to define the proper shape, the “dimensionality” of the lot, which ranges from 0 to 3, must be defined. A zero-dimensional lot exists when the whole lot is used for analysis and, thus, no DE exists, or when the order (through time or space) of the sampling has been lost or is irrelevant (e.g. a processed laboratory sample). Similarly to a zero-dimensional lot, a one-dimensional (1-D) lot may be defined as a thin, continuous, elongated pile or stream, except that the order of the sample is important. For zero- or 1-D lots, a correct sample is obtained by collecting all of the soil between two parallel planes cut across the entire sample. An example of a 1-D lot may be a core sample from which a slice is cut for the analytical subsample.

A 2-D lot is correctly sampled by a cylinder with a constant cross-section and consists of a mass with an upper and lower boundary. The third dimension,
although existing, for a 2-D lot should be insignificant when compared with the other two dimensions. Typical examples of 2-D lots in a soil is a horizon (or a designated sampling layer) in which the thickness of the horizon is negligible compared with its horizontal distribution or a core sample collected through the entire soil horizon.

A 3-D lot is a sample in which all three dimensions are important and significant. Examples of 3-D lots include large waste piles, truck loads of soil, and an entire waste site. 3-D lots are nearly impossible to sample correctly since the proper shape of the sample is a sphere. 3-D samples are typically reduced to 2-D samples for correct subsampling purposes. The 1-D and 2-D lots are most frequently encountered during soil sampling. The 2-D lot is collected in the field whereas the 1-D lot is sampled during sample preparation and analysis.

The other important aspect of DE is that the sampling device must be able physically to collect all particles (or portions of particles) that lie within the edges of the sampling device (Figure 5). If a particle or fraction of particle lies outside the sampling device, then it must be excluded from the collected sample. However, collection of only those portions of particles that lie within the edges of the sampling device is neither practical nor possible since the sampling device cannot cut soil particles. To account for the cutting error associated with the sampling device as it delimits the sample, the increment EE has been defined. To extract a sample properly, the ‘‘rule of the center of gravity’’ must be respected. The rule of the center of gravity simply states that if the center of gravity for a particle lies within the sampling device boundaries, then the fragment must be included with high probability in the sample (Figure 6). Conversely, if the particle’s center of gravity lies outside the sampling device boundaries, yet part of the particle lies within the sampling device’s edges, then the particle must be excluded with high probability from the collected sample (Figure 7). Factors that can affect the center of gravity rule during soil sampling are as follows:

- The straightness of the cutting edge. The tips of the cutting edge should be superposable to each other by simple lateral translation (i.e. both edges of equal length).
- The shape of the cutting edge. The cutting edge should form an angle between the outer wall of the sampler, and the line parallel to the cutting edge should be less than 45° or equal to 90° (a flat cutting edge). If the cutting edge has two beveled edges from the tip, then a right-angle should be formed at the cutter tip between the two sides.
One possible means to minimize the EE is to select a larger diameter coring device. The last two errors, the PE and AE, are the result of physical sample manipulation or from noise in the system. The major sources of PE include contamination, alteration of chemical form (e.g., volatilization or redox reactions), human error, and loss of the sample via misplacement or spillage. PE may be unintentional and occur during sample grinding, sieving, and storage, or through other mistakes such as mislabelling or improper sample handling. Occasionally, intentional error (e.g., fraud or sabotage) may be encountered such that pollutants of concern are intentionally lost during preparation or sampling. AE is the error of which most analysts are cognizant. Unfortunately, it is in reducing, controlling, and quantifying AE that most QA/QC time, effort, and budget are expended. As presented throughout the discussion of particulate sampling theory, without giving proper attention to the actual soil sample collection, the sample received at the analytical laboratory may have already been so severely biased that controlling the AE may hardly be worth the time and expense.

7.3 Application of Particulate Sampling Theory to Soil Sampling

One of the keys to Gy’s theory is that it provides a means to determine the quantity of soil to collect and submit a representative sample with an acceptable and set relative variance of the FE to the analytical laboratory based on the maximum particle diameter. Additionally, if a large sample is submitted, it provides a comminution (i.e., particle-size reduction) protocol to reduce the sample size yet maintain the FE below the acceptable relative variance as defined in the DQO process. Of course, this assumes that the sample is collected correctly using all possible means to control and minimize the GE, DE, EE, PE, and AE, so that these errors are negligible compared with FE. Two approaches used to determine the required sample mass are to calculate the mass by solving for $M_S$ in the FE equation or to create a sampling nomograph (Figure 8). Following the calculational pathway, for example, based on the assumptions of an allowable relative standard deviation (RSD) for FE of 15% (or a relative variance of FE of 0.0225), $M_L \gg M_S$, $d = 2$ mm, $f = 0.5$, $g = 0.25$, $l = 0.2$, $\lambda = 2.65$ g cm$^{-3}$, and contaminant concentrations ($a_L$) = 50, 100, 250, 500, and 1000 ppm, then the required sample weights are approximately 471, 236, 94, 47, and 24 g, respectively. By changing the allowable RSD of FE to 5% and following the same assumptions, the required sample weights would be 4240, 2120, 848, 424, and 212 g, respectively.

A sampling nomograph also allows the sampler to control sampling and sample processing such that no step exceeds the DQO established for allowable FE. The nomograph provides a visual interpretation of steps that may be necessary to reduce particle and sample size in addition to providing the required sample mass for a given maximum particle size. The construction of a nomograph simply involves solving and plotting the equation for the FE. The FE was defined according to Equation (12):

$$s^2_{FE} = \left( \frac{1}{M_S} - \frac{1}{M_L} \right) f g c d^3$$

(12)

This equation can be rearranged to identify a sampling constant, $C$, by assuming constant values for $f$, $g$, $c$, and $l$ and assuming that $M_L$ is much larger (at least 10-fold) than $M_S$. The equation then becomes Equation (13):

$$s^2_{FE} = \frac{C d^3}{M_S}$$

(13)

where $C = f g c l$.

In order to put all the pertinent information on a single nomograph, a logarithmic coordinate system is used and thus the equation becomes Equation (14):

$$\log s^2_{FE} = \log C + 3 \log d - \log M_S$$

(14)
For a given particle size $d$ and a sampling constant $C$, the value of $\log s^2_{FE}$ is directly proportional to $-\log M_S$.\(^{(22)}\) The derivative of $\log s^2_{FE}$ with respect to $M_S$ equals $-1$. Then, the line representing $\log s^2_{FE}$ as a function of $-\log M_S$ for a given particle size $d$ and a sampling constant $C$ has a slope of $-1$ on the nomograph. Therefore, to plot the nomograph for a given $d$ with a constant $C$, $\log s^2_{FE}$ is plotted on the y-axis, $\log M_S$ is plotted on the x-axis, and $\log d$ is plotted as a family of parallel lines with a slope of $-1$ (Figure 8).

To identify a minimum required sample size given the largest particle diameter and acceptable relative variance limit, the sampler can follow the diagonal particle size line to the point where it intersects the horizontal variance line. At the point of intersection, the value on the x-axis equals the minimum sample size required to collect a representative sample.

Alternatively, if a large sample is collected whose mass must be reduced to a smaller size (e.g. to the size required for an extraction procedure), the nomograph provides information on how to reduce the sample mass without exceeding the acceptable DQO relative variance level. To identify the steps necessary (if any) to reduce the sample mass properly, the sampler needs to know the acceptable relative variance limit in addition to the starting and final sample weights. Following the same process for determining the required sample size, if the intersection of the particle size and variance lines results in a sample size smaller than the final required weight, then no particle size reduction is necessary, and the sample can be collected bearing in mind to minimize the other sampling errors. If not, then some form of particle size reduction (i.e. comminution) must be taken. The reduction in particle size can be performed by grinding, correct splitting, or by screening the sample to remove larger particle sizes.\(^{(23)}\) The removal of the coarsest particle sizes should be based on the assumption that the largest particles do not contribute significantly to the contaminant concentration. To select an appropriate particle reduction scheme, simply follow the maximum particle diameter line from its intersection with the starting weight line until it intersects the acceptable variance line. At this point, a vertical line should be drawn until it intersects a smaller particle diameter line that falls below the variance line for the final required sample size. Once an appropriate smaller particle diameter line has been identified, then the whole sample needs to be reduced to have the coarsest particles equal to or smaller than that selected diameter. Several steps may be required to reduce the maximum particle sizes properly but the key is to not go above the acceptable relative variance limit.

7.4 Selection of Sampling Equipment

The selection of sampling equipment should be performed with care since the sampling equipment must be able to collect a representative and correct sample and because the sampling equipment comes in direct contact with the soil. Criteria that should be considered during the selection of the appropriate sampling tool are chemical and physical compatibility, matrix effects, volume capacity, physical requirements for equipment use, ease of
operation, time requirement, decontamination and reuse potential, cost, and soil type to be sampled.\(^{16,24,25}\) Further, the appropriate sampling device(s) selected must be correct with respect to delimitation and EEs previously discussed. Each of these factors will be discussed in greater detail in the following text.

Since the soil comes into direct contact with the sampling tool, the sampling tool must be compatible both chemically and physically with the soil and the contaminants present in the soil.\(^{24}\) Chemical compatibility is a concern primarily when organic contaminants are present. The sampling tool should not be a source of additional sample contamination and should be free from (or at least resistant to) chemical degradation that may occur due to interactions with the samples. For example, plastic or acetate sleeves commonly used as liners in coring equipment should be avoided when sampling for organics because they can “bleed” phthalates and other organic compounds into the sample as well as degrade owing to the “solvent” effect of some organics that may be present in the contaminated soil. Conversely, certain organic contaminants may partition into the plastic resulting in lower contaminant concentrations and cross-contamination if the plastic sampler is used to obtain another sample. Physical compatibility is a consideration in terms of the physical strength of the sampler to resist deformation when collecting the soil and for the possibility of sample contamination due to physical abrasion of the sampler, with the separated particles becoming part of the analytical sample. For example, the use of stainless-steel sampling equipment for sampling chromium-contaminated soils should be avoided since chromium is a major elemental component in stainless steel.

The effect of the sampling device on the soil matrix is an important concern because the design of the device influences the representativeness of the collected sample.\(^{24}\) As previously discussed, if the sampling device excludes a given particle-size fraction (Gy’s increment EE) or improperly collects the sample by influencing which part of the whole sample is collected (Gy’s increment delineation error), then major sources of error enter into the sampling and analytical stream. Further, sample disturbance is a primary consideration when sampling soil for VOCs. An intact core is highly preferred (versus a disagggregated sample obtained from devices such as augers) during collection of VOC-contaminated soils since the minimization of atmospheric exposure of the sample and consequent VOC loss from the sample is imperative.

Most sampling devices provide adequate sample volume.\(^{24}\) However, sampling device volumes should be compared with the volume necessary for all required analyses and, QA purposes, and provide sufficient excess sample for archiving and reanalyses purposes. If the device does not provide adequate volume, the following options should be considered: collecting multiple increments/samples in very close proximity to the original location, using a similar device with increased capacity, using an alternate device with increased capacity, or modifying the existing device.

The physical requirements, ease of operation, and time required for use of the sampling equipment all relate to the transport and operation of the selected sampling device.\(^{24}\) Physical requirements to be considered are the device’s size and weight since the sampler may have to carry the device to the sampling location and manually collect the sample. If the device is power driven, then the power source and ancillary equipment (e.g., drill rigs, trucks) are a concern in selecting these devices. Ease of operation concerns involve the training of personnel to use the sampling device effectively and properly. Fortunately, most manually operated sampling equipment is relatively simple to use, and representative samples can be collected as long as proper care is taken during sample collection. A factor influencing both the ease of operation and time requirement for sampling is the labor requirement. Most power-driven sampling tools require multiple-person teams to effectively and safely use the equipment but have the advantage of shorter sample collection times, especially when depths exceed 1 m (39 in). In contrast, manual sampling tools, while allowing a single sampler to collect surface samples quickly and efficiently, require much longer times to collect samples at depth than power-driven tools.

Decontamination, reuse potential, and cost are concerns when sampling equipment may be used for multiple sampling programs.\(^{24}\) Three aspects of decontamination, and thus the device’s reuse potential, to consider are the procedure’s ease, success (i.e., ability to eliminate or minimize the potential for sample cross-contamination), and time involved. Ideally, the decontamination procedure should be simple, quick, and successful. Most soil sampling equipment can be effectively decontaminated with a simple soap and water wash followed by water rinse. However, where certain organic compounds are of concern, a solvent rinse may also be necessary. [Note: caution should be taken during the selection and use of solvents to rinse sampling equipment to avoid cross-contamination of the samples, health and safety issues, and spillage such that the solvents become part of the problem at the site.] If successful decontamination procedures are not possible owing to the soil matrix or contaminant (e.g., soil contaminated with heavy oils or tars), the use of disposable sampling tools should be considered to avoid sample cross-contamination. Cost considerations should be contemplated and compared with the life expectancy of the equipment and use expectancy (i.e., will the equipment be used for multiple projects within the organization or should it be leased for a short one-time project).
Several soil types make the routine collection of soil samples difficult and thus require specialized (or modified) sampling tools. These soil types include stony soils, noncohesive soils, and saturated (or nearly saturated) soils.\(^{(16,24)}\) Sampling difficulties are encountered in stony soils owing to the blocking or plugging of the device’s opening, thus preventing the collection of the sample. Large stones may also prevent the penetration of the sampling device to any significant depth. Noncohesive soils, such as loose sands, require special sampling equipment that retains the soil within the sampler and thus prevents the soil from flowing out of the open end of the sampling device. In contrast, saturated soils (e.g. mucks and muds) are generally difficult to collect and remove from the sampling tool, especially if the soils have high clay contents. Under these circumstances, specialized sampling tools are required that will allow for the simple removal of the soil from the sampling device.

### 7.5 Soil Sampling Tools

Soil sampling tools can be divided into two main categories based on the depth to which the samples can be collected. Surface samplers are generally designed to

\(^a\) This table does not purport to be exhaustive. Only the general names of the sampler types are presented. Varying names for the same sampler or same type of sampler with slight modifications are commonly identified in the literature and sales catalogs.

\(^b\) Approximate lengths and internal diameters (i.d.), in inches.

\(^c\) Var = variable depending upon length of sampler or size of hole dug; Coh = cohesive; Non = noncohesive; Int = intermediate wetness (i.e. not dry nor wet); Multi = two or more persons required to operate effectively.

\(^d\) Manual auger lengths given are just for portion of the sampler where the actual sample is held. Most bucket augers have handles and extensions that allow for greater sampling depths with multiple passes.

\(^e\) Manually operated versions of these samplers can be operated by one person.
collect the sample within the upper 30 cm (12 in) with a single pass (i.e. single insertion into the soil) of the sampling device. Subsurface devices are generally designed to sample to a depth of 1.5 m (60 in) in a single pass but can usually collect deeper samples with multiple passes. Table 1 presents commonly available sampling tools and information on the selection criteria previously discussed. Project-specific parameters, such as compatibility, matrix effects, decontamination requirements, and cost will need to be determined on a per-project basis.

While spoons, scoops, trowels, and shovels (or backhoes) are perhaps the most readily available and widely used sampling tools for the collection of surface samples, they also tend to introduce the greatest sampling error. The most common cause of the sampling error is the improper increment delimitation in which part of the sample is unintentionally excluded from the sample to be analyzed. For example, when using a shovel, rarely is the hole dug such that the side walls are parallel to each other and perpendicular to the surface. The natural tendency is to dig a hole with side walls at an angle to the surface (Figure 9c). If the sample collected from the soil is removed from the hole, the lower portion of the sample is under-represented since less sample is collected at that depth than at the wider surface mouth. Under these circumstances, if the contaminant has been leached to a depth within a given sampling increment, a lower contaminant concentration may be obtained due to sample “dilution” with the cleaner overlying material. Conversely, if the contaminant is present at or near the surface, then the reported concentrations may overestimate the actual concentration due to inclusion of a greater proportion of surface versus subsurface soil. To overcome this problem, it is recommended to dig a hole to the required depth and collect the sample from the walls of the hole being careful to collect a uniform sample thickness from the entire length of the sampling stratum. Alternatively, care must be taken to dig the hole properly to include equal proportions of all fractions within the sampling increment (Figures 9a and b).

The same general principle is the basis for the error introduced when using spoons, scoops, and trowels. Most of these samplers have a rounded bottom which, when used to collect soil, preferentially collects less of the lower portion of the sample than the surface and thus biases the results (Figure 10a). Additionally, since none of these sampling utensils have side walls capable of holding the entire sample within the sampler, as the sample is removed and transported to the sample container, portions of the sample may be lost by “falling” off the sampler (Figure 11a). In some cases, both the upper and lower portion of the sample may be lost with the greatest sampled portion being collected from the middle of the sampling stratum. To collect a sample properly with these types of tools would require equipment modification to have parallel side walls and a flat bottom capable of holding the entire sampling increment (Figures 10b and 11b).

Tube-type samplers, including probes, punches, corers, tube samplers, barrel samplers, continuous samplers, and zero contamination samplers, tend to have a distinct advantage over other forms of samplers since an intact soil core is collected. The cylindrical shape of the intact core is the correct shape for a 2-D lot and, thus, reduces
the increment DE as long as care is taken to collect the entire layer or depth defined as the sampling increment (Figures 9a and b).222

When more sample is collected than required for the sampling increment [e.g. a 25-cm (10-in) core is collected and subsampled to collect the top 10 cm (4 in)], care must be taken to delineate the proper increment by cutting the new boundary parallel to the surface of the sample at the desired depth. For the thinner diameter tube-type samplers (<2.5 cm i.d.; 1 in), the increment EE may be a concern owing to exclusion of larger particles at the mouth of the sampling tube.

Augers, whether used to collect surface or subsurface samples, with the exception of the hollow-stem auger, collect samples that are disaggregated by the cutting bit or within the auger threads. This cutting action destroys natural soil structure and makes it difficult to delineate accurately soil horizon boundaries or sampling depths. This disaggregating property of augers also makes them unsuitable for the collection of soils contaminated with VOCs since the sample disturbance allows for the rapid loss of VOCs to the atmosphere. Increment DE may also occur with augers since the lowest portion of the sample (i.e. that portion where threads do not overlap and have an upper and lower thread to hold the sample) cannot be collected.

Thief and triers are two types of sampling tools that were not designed for the collection of soils but can be used when necessary. Thiefs are usually pushed into the sample and rotated to open “windows” and allow the sample to flow into the central chamber/barrel to be collected.24 This type of filling action leads to the concerns about incorrect sample delimitation since (a) the sample below the windows, although truly a part of the sample, cannot be collected, (b) only those particles that flow easily are collected, (c) particles larger than the window diameter are excluded, thus biasing the collected sample to the finer particle sizes, and (d) the proper cylindrical shape for a 2-D lot is not guaranteed. Triers, on the other hand, while nearly capable of collecting the proper sample cylinder, do not have side walls to hold the sample once collected. This lack of side walls can lead to sample loss during sample removal and transfer operations, resulting in potentially biased analytical results.

**8 SAMPLE HANDLING AND PREPARATION**

Once the sample has been collected, the next steps that occur prior to preparing subsamples for analysis are sample handling and preparation. Various concerns and steps are involved which are briefly presented here to remind the sampler of their final responsibilities. These steps include sample compositing, homogenization, preservation, and storage.

Sample compositing is the process of combining several distinct subsamples to create a single sample for analysis.26 The combined subsamples are then homogenized to make up the final sample submitted for analysis. The advantages of composite sampling are that it reduces the cost of analysis at a waste site and provides an estimate of the mean concentration. If the sampler follows the principles of Gy’s particulate sampling theory, then sample compositing after the collection of numerous small increments is an excellent way to reduce GE. The disadvantages of sample compositing are a loss of information about variation within the sampling area,27 loss of sensitivity because of sample dilution,28 and the time required to homogenize the samples prior to laboratory subsampling. In situations where rapid, field-portable methods are used (e.g. field portable X-ray fluorescence spectrometry), compositing may not be necessary since individual samples can be analyzed in real time to provide a more definitive answer concerning the distribution of a contaminant at the waste site.

Numerous techniques have been used to homogenize soils prior to the removal of the analytical subsample.29,30 Some of these techniques include bottle shaking, stirring, sheet mixing or rolling, tumbling, mechanical mixing (e.g. cement mixers or V-blenders), riffling, cone-and-quartering, and sectorial splitting. Homogenization is performed to diminish GE within the sample or lot. When performing sample homogenization, perhaps the most frequently asked question is “when has homogeneity been reached?”. Although there is no patented answer to this question, most investigators will “homogenize” their samples for a fixed time, a fixed number of passes, or until visual homogeneity is reached without ever testing the degree of sample homogeneity. Investigators should always test their homogenization technique prior to full-scale usage especially since some “homogenizers” will actually lead to resegregation of the sample.

In one experiment to determine the effectiveness (degree of homogeneity) and the efficiency (time consumption) of riffling versus cone-and-quartering as homogenization techniques, it was found that using a closed-bin riffler splitter (which also reduced visual fine particle loss) was more consistently effective and efficient than cone-and-quartering, open-bin riffling splitting, or random sampling, when the sample was passed through the riffler splitter five times.30 In this experiment, homogenization was performed on bulk soils (approximately 5 kg each with textures ranging from sand through clay) by either pouring the soil collected in both bins back through
the riffle splitter, or by forming a new cone as the individual quarters are removed during cone-and-quartering. While homogenization can help overcome grouping and segregation problems that occur during shipment and handling, properly performed incremental sampling can also produce the same benefits without the added time and expense.\(^{(23)}\)

Sample preservation for most soil samples is simply to cool the sample to 4 °C or colder.\(^{(31)}\) For soils contaminated with VOCs, “preservatives” such as methanol or other biocides are commonly used, in conjunction with cooling, to help reduce biological degradation and volatilization of the VOCs. Sample storage in either plastic or glass containers is generally acceptable for soils contaminated with inorganics. In contrast, organically contaminated soils should be stored in glass containers (with Teflon™-lined caps for VOC-containing soils). It should be noted that some compounds are light-sensitive, and such samples should be stored in the dark to avoid any photochemical reactions.

**ACKNOWLEDGMENTS**

The work presented here was based on an original chapter prepared by the authors for the *Encyclopedia of Environmental Analysis and Remediation*.\(^{(32)}\) The US Environmental Protection Agency (EPA), through its Office of Research and Development, funded and performed the research described. Solid-phase microextraction (SPME) uses a small volume of sorbent dispersed typically on a surface of small fibers to isolate and concentrate analytes from a sample matrix. After contact with the sample, analytes are absorbed or adsorbed by the fiber phase (depending on the nature of the coating) until an equilibrium is reached in the system. The amount of an analyte extracted by the coating at equilibrium is determined by the magnitude of the partition coefficient of the analyte between the sample matrix and the coating material. After the extraction step, the fibers are transferred, with the help of the syringe-like handling device, to an analytical instrument, for separation and quantitation of target analytes. This technique is able to integrate sampling, extraction and sample introduction in a simple way, facilitating on-site monitoring. The additional advantages include elimination of solvents from the sample preparation step and convenient introduction of extracted components into the analytical instrument. Applications of this technique to date include environmental, industrial hygiene, process monitoring, clinical, forensic, food and flavor, fragrance and drugs, in laboratory and on-site analysis.

1 INTRODUCTION

SPME was developed to address the need for fast, solvent-free and field-compatible sample preparation technologies. The information presented below is a summary of the comprehensive discussion of the topic covered in a published book.\textsuperscript{(1)}

SPME was introduced as a solvent-free sample preparation technique in 1990. The basic principle of this approach is to use a small amount of the extracting phase, usually less than one microliter. The sample volume can be very large, when the investigated system, for
example air in room or lake water, is sampled directly. The extracting phase can be either a high-molecular-weight polymeric liquid, similar in nature to stationary phases in chromatography, or it can be a solid sorbent, typically of a high porosity to increase the surface area available for adsorption.

To date the most practical geometric configuration of SPME utilizes a small fused-silica fiber, usually coated with a polymeric phase. The fiber is mounted for protection in a syringe-like device. The analytes are absorbed or adsorbed by the fiber phase (depending on the nature of the coating) until an equilibrium is reached in the system. The amount of an analyte extracted by the coating at equilibrium is determined by the magnitude of the partition coefficient (distribution ratio) of the analyte between the sample matrix and the coating material.

In SPME, analytes typically are not extracted quantitatively from the matrix. However, equilibrium methods are more selective because they take full advantage of the differences in extracting-phase/matrix distribution constants to separate target analytes from interferences. Exhaustive extraction can be achieved in SPME when the distribution constants are large enough. This can be accomplished for most compounds by the application of internally cooled fiber. In exhaustive extraction, selectivity is sacrificed to obtain quantitative transfer of target analytes into the extracting phase. One advantage of this approach is that, in principle, it does not require calibration, since all the analytes of interest are transferred to the extracting phase. On the other hand, the equilibrium approach usually requires calibration when dealing with complex matrices. This is accomplished by using surrogates or standard addition to quantify the analytes and compensate for matrix-to-matrix variations and their effect on distribution constants.

Since equilibrium rather than exhaustive extraction occurs in microextraction methods, SPME is ideal for field monitoring. It is unnecessary to measure the volume of the extracted sample and therefore the SPME device can be exposed directly to the investigated system for quantitation of target analytes. In addition, extracted analytes are introduced to the analytical instrument by simply placing the fiber in the desorption unit (Figure 1b and c). This convenient, solvent-free process facilitates sharp injection bands and rapid separations. These features of SPME result in integration of the first steps in the analytical process: sampling, sample preparation and introduction of the extracted mixture to an analytical instrument.

The equilibrium nature of the technique also facilitates speciation in natural systems since the presence of a minute fiber, which removes small amounts of target analytes, is not likely to disturb the system. Because of the small size, coated fibers can be used to extract analytes from very small samples. For example, SPME has been

used to probe for substances emitted by a single flower bulb during its lifespan.

Figure 1(a) illustrates the commercial SPME device, manufactured by Supelco, Inc. (Bellefonte, PA). The
fiber, glued into a piece of stainless steel tubing, is mounted in a special holder. The holder is equipped with an adjustable depth gauge, which makes it possible to control repeatedly how far the needle of the device is allowed to penetrate the sample container (if any) or the injector. This is important, as the fiber can be easily broken when it hits an obstacle. The movement of the plunger is limited by a small screw moving in the z-shaped slot of the device. For protection during storage or septum piercing, the fiber is withdrawn into the needle of the device, with the screw in the uppermost position. During extraction or desorption, the fiber is exposed by depressing the plunger, which can be locked in the lowered (middle) position by turning it clockwise (the position depicted in Figure 1a). The plunger is moved to its lowest position only for replacement of the fiber assembly. Each type of fiber has a hub of a different color. The hub-viewing window enables a quick check of the type of fiber mounted in the device.

If the sample is placed in a vial, the septum of the vial is first pierced with the needle (with the fiber in the retracted position), and the plunger is lowered, which exposes the fiber to the sample. The analytes are allowed to partition into the coating for a predetermined time, and the fiber is then retracted back into the needle. The device is next transferred to the analytical instrument of choice. When gas chromatography (GC) is used for analyte separation and quantitation, the fiber is inserted into a hot injector, where thermal desorption of the trapped analytes takes place (Figure 1c). The process can be automated by using an appropriately modified syringe autosampler. For high-performance liquid chromatography (HPLC) applications, a simple interface mounted in place of the injection loop can be used to re-extract analytes into the desorption solvent (Figure 1b).

A SPME device is capable of both spot and time-averaged sampling. As described above, for spot sampling, the fiber is exposed to a sample matrix until the partitioning equilibrium is reached between the sample matrix and the coating material. In the time-averaged approach, on the other hand, the fiber remains in the needle during the exposure of the SPME device to the sample. The coating works as a trap for analytes that diffuse into the needle, resulting in an integral of concentration over time measurement.

SPME sampling can be performed in three basic modes: direct extraction, headspace extraction, and extraction with membrane protection. Figure 2 illustrates the differences between these modes. In direct extraction mode (Figure 2a), the coated fiber is inserted into the sample and the analytes are transported directly from the sample matrix to the extracting phase. To facilitate rapid extraction, some level of agitation is required to transport the analytes from the bulk of the sample to the vicinity of the fiber. For gaseous samples, the natural flow of air (e.g., convection) is frequently sufficient to facilitate rapid equilibration for volatile analytes, but for aqueous matrices, more efficient agitation techniques, such as fast sample flow, rapid fiber or vial movement, stirring or sonication are required to reduce the effect of the “depletion zone” produced close to the fiber as a result of slow diffusional analyte transport through the stationary layer of liquid surrounding the fiber.

In the headspace mode (Figure 2b), the analytes are extracted from the gas phase equilibrated with the sample. The primary reason for this modification is to protect the fiber from adverse effects caused by non-volatile, high-molecular-weight substances present in the sample matrix (e.g., humic acids or proteins). The headspace mode also allows matrix modifications, including pH adjustment, without affecting the fiber. In a system consisting of a liquid sample and its headspace, the amount of an analyte extracted by the fiber coating does not depend on the location of the fiber, in the liquid phase or in the gas phase, therefore the sensitivity of headspace sampling is the same as the sensitivity of direct sampling as long as the volumes of the two phases are the same in both sampling modes. Even when no headspace is used in direct extraction, a significant sensitivity difference between direct and headspace sampling can occur only for very volatile analytes. However, the choice of sampling mode...
has a very significant impact on the extraction kinetics. When the fiber is in the headspace, the analytes are removed from the headspace first, followed by indirect extraction from the matrix. Therefore, volatile analytes are extracted faster than semivolatiles. Temperature has a significant effect on the kinetics of the process, since it determines the vapor pressure of analytes. In general, the equilibration times for volatile compounds are shorter for headspace SPME extraction than for direct extraction under similar agitation conditions, for the following three reasons:

1. a substantial portion of the analytes is present in the headspace prior to the beginning of the extraction process;
2. there is typically a large interface between sample matrix and headspace; and
3. the diffusion coefficients in the gas phase are typically higher by four orders of magnitude than in liquids.

The concentration of semivolatile compounds in the gaseous phase at room temperature is small, so headspace extraction rates for those compounds are substantially lower. They can be improved by using very efficient agitation or by increasing the extraction temperature.

In the third mode (SPME extraction with membrane protection, Figure 2c), the fiber is separated from the sample with a selective membrane, which lets the analytes through while blocking the interferences. The main purpose of the membrane barrier is to protect the fiber against adverse effects caused by high-molecular-weight compounds when very dirty samples are analyzed. While extraction from headspace serves the same purpose, membrane protection enables the analysis of less volatile compounds. The extraction process is substantially slower than direct extraction because the analytes need to diffuse through the membrane before they can reach the coating. Use of thin membranes and increase in extraction temperature result in shorter extraction times.

2 THEORETICAL ASPECTS OF SOLID-PHASE MICROEXTRACTION OPTIMIZATION AND CALIBRATION

2.1 Thermodynamics

SPME is a multiphase equilibration process. Frequently, the extraction system is complex, as in a sample consisting of an aqueous phase with suspended solid particles having various adsorption interactions with analytes, plus a gaseous headspace. In some cases specific factors have to be considered, such as analyte losses by biodegradation or adsorption on the walls of the sampling vessel. In the discussion below we will only consider three phases: the fiber coating, the gas phase or headspace and a homogeneous matrix such as pure water or air. During extraction, analytes migrate between all three phases until equilibrium is reached.

The mass of an analyte extracted by the liquid polymeric coating is related to the overall equilibrium of the analyte in the three-phase system. Since the total mass of an analyte should remain constant during the extraction, we have Equation (1):

\[
C_0 V_s = C_f^\infty V_f + C_h^\infty V_h + C_s^\infty V_s
\]

(1)

where \( C_0 \) is the initial concentration of the analyte in the matrix; \( C_f^\infty \), \( C_h^\infty \), and \( C_s^\infty \) are the equilibrium concentrations of the analyte in the coating, the headspace, and the matrix, respectively; \( V_f \), \( V_h \), and \( V_s \) are the volumes of the coating, the headspace, and the matrix, respectively. If we define the coating/gas distribution constant as \( K_{fh} = C_f^\infty / C_h^\infty \), and the gas/sample matrix distribution constant as \( K_{gs} = C_h^\infty / C_s^\infty \), the mass of the analyte absorbed by the coating, \( n = C_f^\infty V_f \), can be expressed as Equation (2):

\[
n = \frac{K_{fh} K_{hs} V_f C_0 V_f}{K_{fh} K_{hs} V_f + K_{hs} V_h + V_s}
\]

(2)

Also (Equation 3):

\[
K_{hs} = K_{fh} K_{hs} = K_{fh} K_{gs}
\]

(3)

since the fiber/headspace distribution constant, \( K_{fh} \) can be approximated by the fiber/gas distribution constant \( K_{fs} \), and the headspace/sample distribution constant, \( K_{hs} \), by the gas/sample distribution constant, \( K_{gs} \), if the effect of moisture in the gaseous headspace can be neglected. Thus, Equation (2) can be rewritten as Equation (4):

\[
n = \frac{K_{fs} V_f C_0 V_s}{K_{fs} V_f + K_{hs} V_h + V_s}
\]

(4)

Equation (4) states, as expected from the equilibrium conditions, that the amount of analyte extracted is independent of the location of the fiber in the system. It may be placed in the headspace or directly in the sample as long as the volumes of the fiber coating, headspace and sample are kept constant. There are three terms in the denominator of Equation (4) which give measures of the analyte capacity of each of the three phases: fiber \( (K_{fs} V_f) \), headspace \( (K_{hs} V_h) \), and the sample itself \( (V_s) \). If we assume that the vial containing the sample is completely filled (no headspace), the term \( K_{gs} V_h \) in the denominator, which is related to the capacity \( (C_s^\infty V_s) \) of the headspace, can be eliminated, resulting in Equation (5):

\[
n = \frac{K_{fs} V_f C_0 V_s}{K_{fs} V_f + V_s}
\]

(5)
Equation (5) describes the mass absorbed by the polymeric coating after equilibrium has been reached in the system. In most of determinations, $K_{fg}$ is relatively small compared to the phase ratio of sample matrix to coating volume ($V_f \ll V_s$). In that situation the capacity of the sample is much larger compared to capacity of the fiber resulting in a very simple relationship (Equation 6):

$$n = K_{fg} V_f C_0$$  \hspace{1cm} (6)

Equation (6) emphasizes the field sampling capability of the SPME technique. It is not necessary to sample a well-defined volume of the matrix since the amount of analyte extracted is independent of $V_s$ as long as $K_{fg} V_f \ll V_s$. The SPME device can be placed directly in contact with the investigated system to allow quantitation.

Strictly speaking, the above discussion (Equations 4–6) is limited to the partitioning equilibrium involving liquid polymeric phases such as PDMS. The method of analysis for solid sorbent coatings is analogous for low analyte concentration, since the total surface area available for adsorption is proportional to the coating volume if we assume constant porosity of the sorbent. For high analyte concentration the saturation of the surface can occur resulting in nonlinear isotherms. Similarly high concentration of a competitive interference compound can displace the target analyte from the surface of the sorbent. The simplest way to consider these high-concentration effects is to replace the volume of the fiber coating, $V_f$ in the above equations as a measure of the total fiber surface area, by a fraction of the original coating volume corresponding to a free surface area available for adsorption.

### 2.1.1 Prediction of Distribution Constants

In many cases, the distribution constants present in Equations (4–6) which determine the sensitivity of SPME extraction can be estimated from physicochemical data and chromatographic parameters. This approach eliminates the need for calibration. For example, distribution constants between a fiber coating and gaseous matrix (e.g. air) can be estimated using isothermal GC retention times on a column with a stationary phase identical to the fiber coating material. This is possible because the partitioning process in GC is analogous to the partitioning process in SPME, and there is a well-defined relationship between the distribution constant and the retention time. The nature of the gaseous phase does not affect the distribution constant, unless the components of the gas, such as moisture, swell the polymer, thus changing its properties. A most useful method for determining coating-to-gas distribution constants uses the linear temperature programmed retention index (LTPRI) system, which indexes compounds' retention times relative to the retention times of $n$-alkanes. This system is applicable to retention times for temperature programmed gas–liquid chromatography. The logarithm of the coating-to-air distribution constants of $n$-alkanes can be expressed as a linear function of their LTPRI values. For PDMS, this relationship is $\log K_{fg} = 0.00415 \times \text{LTPRI} - 0.188$. (5)

Thus, the LTPRI system permits interpolation of the $K_{fg}$ values from the plot of $\log K_{fg}$ versus retention index. The LTPRI values for many compounds are available in the literature, hence this method allows estimation of $K_{fg}$ values without experimentation. If the LTPRI value for a compound is not available from published sources, it can be determined from a GC run. Note that the GC column used to determine LTPRI should be coated with the same material as the fiber coating.
